Acknowledgements

First and foremost, I would like to thank my primary supervisor, Associate Professor Mark Jermy, whose expertise and guidance made this research project possible. I am grateful for the opportunity you have given me to pursue this research.

I would also like to extend my gratitude to my secondary supervisor, Dr. Patrick Geoghegan, and my advisor, Dr. Callum Spence. The insight, support and mentorship that you have provided has been invaluable.

To my friends and colleagues in the airway group: Jonathan Aplin, Cletus Adams, Natalia Kabaliuk and the remainder of the team based in The University of Auckland. Thank you for all your help, valuable advice and banter. It has been an absolute pleasure to work alongside you.

I would also like to give a special thanks to the contributions from the technical staff in the Mechanical Engineering department at the University of Canterbury: David Read, Kevin Stobbs, Gary Cotton, and Eric Cox. Also, thank you to Jasgir Khera, at Fisher & Paykel Healthcare.

To MBIE Smart Ideas Grant for funding the project and to Fisher & Paykel Healthcare for giving me the opportunity to carry out this study.

To Emma Murphy. You have motivated me through this project and have helped me through times of doubt. You have my sincerest gratitude.

Lastly, I would like to thank my parents, whom I owe so much. All your love, support and teachings has helped to guide me through my life. Kocham was z całego serca.

Abstract

Nasal high flow therapy (NHFT) has been previously studied on anatomically correct physical airway models using a benchtop setup. In the current study it was desired to elaborate on previous work by incorporating physiological accuracy in the model by simulating the compliance of the internal soft tissues in the airway. Three tissues of interest were investigated: the soft palate, the tongue and the vocal folds. A multi-part mouth open airway model was designed to fit interchangeable compliant structures and fabricated using 3D printing. The model was tested with soft and rigid inserts to compare between compliant and rigid boundary conditions, respectively. Compliance was simulated by fabricating the soft inserts with a silicone resin that matched the elastic modulus of the relevant biological tissues. Pressure measurements were conducted along the airway at different points using pressure sensing probes that were inserted in specially designed taps located along the model. Breathing was simulated using a pulsatile pump and experiments were carried out for natural and NHFT assisted breathing. It was discovered that the soft palate was the only compliant structure that affected the pharyngeal airway pressures for all tested breathing cases. During natural breathing, the compliant soft palate caused pharyngeal pressures to be more negative at peak inspiration by 15.5 ± 5.7 % to 35.3 ± 12.1 % of the corresponding peak-to-peak pressures of the rigid airway model. Greater pressures were measured in the pharynx at peak expiration, with an increase by 3.8 ± 2.6 % to 10.7 ± 2.7 %. During NHFT assisted breathing at 30 L/min, the compliant airway experienced a greater peak inspiratory pressure at the velopharynx only with an increase of 8.0 ± 5.5 %, and globally increased peak expiratory pressures by 9.3 ± 1.1 % to 23.7 ± 5.5 %. During NHFT assisted breathing at 60 L/min, peak inspiratory and expiratory pressures were greater than corresponding airway pressures in the rigid model. Peak inspiratory pressures increased by 6.7 ± 4.6 % to 20.6 ± 7.6 % and expiratory pressures increased by 27.9 ± 4.4 % to 45.6 ± 10.6 %. It was hypothesised that flow induced motion of the compliant soft palate increased the resistance to the air flowing through the oral cavity and hence why it affected the pressures globally throughout the airway. The tongue and vocal folds showed no statistically significant difference, concluding that the compliance of these tissues does not affect breathing pressures. The capnography experiments concluded that, once again only soft palate compliance affected CO₂ gas mixing; however, this was limited to the oral cavity region and only for the NHFT assisted conditions.

The results for the current study show the mean of the $E_t\text{CO}_2$ values in the lower pharynx (taps 18, 23, 24 and 28).	137

1 Introduction

1.1 Nasal High Flow Therapy

Nasal high flow therapy (NHFT) is a respiratory intervention method, which administers supplementary air at high flow rates. It is a non-invasive breathing therapy, supplied to the patient via a nasal cannula. It is generally applied to a patient that can breathe spontaneously, however suffers a respiratory disorder, such as chronic obstructive pulmonary disease (COPD) or asthma, which has increased the patient's work of breathing. The delivered gas is treated to 37°C and 100 % relative humidity, to match body conditions, which allows safe application of air at high flow rates between 10 – 60 L/min in adults and up to 12 L/min in infants. This is a relatively new therapy, and it is not entirely understood, however Dysart et al. (2009) proposed five mechanisms of action:

1. The washout of the nasopharyngeal dead space by flushing out CO₂.
2. Reduction of work of breathing due to adequately high flow rates which match inspiratory demand.
3. Humidified and warmed air improves pulmonary conductance, compared to dry, cold gases.
4. Humidified and warmed air reduces the metabolic cost of conditioning inspired air.
5. High flow rates increase positive pressure in the airway and promote lung recruitment.

1.2 Project Purpose

There have been numerous studies in the past which have endeavoured to understand the air flow mechanics in the human upper airway during natural breathing and NHFT assisted breathing. These studies have used *in vitro* experimental techniques and computational methods on anatomically correct human upper airway models (Adams et al., 2016; Dey, 2014; Spence et al., 2011; Spence et al., 2010; Stringer et al., 2010; Van Hove et al., 2016). The airway models in the past studies have been based on computed tomography (CT) scans, hence their anatomical accuracy. However, due to the limitations of the methods used in the past studies, it has been assumed that the airway passage had a rigid boundary condition. The *in vitro* studies fabricated airway models by either 3D printing from rigid plastic material, or cast in rigid silicone, and in the computational studies, a non-deformable mesh had been used. Modelling the airway as a rigid passage is not a realistic boundary condition, as the airway is surrounded by soft, compliant tissues. In physiology, compliance is a biological tissues' tendency to recoil to its original dimensions.

The purpose of the current research project was to scrutinize the rigid airway boundary assumption, by investigating the effects of compliance during natural and NHFT assisted breathing. It was hypothesised that during respiration, the internal, compliant tissues would undergo flow-induced deformation, due to the force exerted from wall shear stress and static pressure. Deformation of the compliant regions will in turn alter the flow pattern in the airway. Three compliant tissues were investigated in this project, these were: the soft palate, tongue and the vocal folds. In this project, airway compliance was experimentally investigated with a physical airway model which was designed to replicate the compliance of the tissues of interest and a rigid boundary condition. Pressure tests and capnography were carried out on both rigid and compliant airway conditions during simulated breathing, to assess the influence of compliance. The research project proposed the following questions:

- How do you simulate compliance in a benchtop model?
- What compliant structures affect airway pressures and CO₂ gas mixing during respiration and to what extent?
- How does this vary with NHFT?

1.3 Thesis Structure

The thesis is comprised of the following sections. Chapter 2 sheds light on the anatomy and physiology of the respiratory system. The anatomy of the compliant tissues of interest is also explained. Chapter 3 reviews previous studies that are relevant to the project. This involves airway modelling and studies into NHFT. It also explores previous studies into airway compliance and mechanical properties of the compliant tissues of interest. Chapter 4 explains the procedures carried out to fabricate the compliant airway model. Chapter 5 explains the system hardware and software used in the experiments. Chapter 6 describes the flow measurements to measure the distribution of inspired and expired air flow rate in the outlets of the airway model. Chapter 7 explains the experimental procedure for the pressure tests and chapters 8- 10 goes through the pressure results. Chapter 11 describes the experimental procedure for the capnography and the results.

2 Background Information

2.1 Anatomy of the Respiratory System

To begin, the anatomical terms of location are introduced as these will be referred to throughout the thesis. Anatomical planes and directions are summarized in Figure 1. Superior describes the position above something and inferior describes the position below something. Similarly, anterior refers to the front and posterior refers to the back. Proximal describes the direction towards the main body and distal is the direction away from the main body. Left and right are self-explanatory. The coronal, sagittal and axial planes are the anatomical equivalent to front, side and top engineering planes, respectively.

Figure 1. Anatomical planes and terms of location. Adapted from Boundless (2016)

The respiratory and cardiovascular systems facilitate the exchange between oxygen (O_2) and carbon dioxide (CO_2) in the body. There are three categories of gas exchange that can occur: pulmonary ventilation, the exchange between the atmospheric air and the air in the lungs via inspiration and expiration; external respiration, the gas exchange between air in the lungs and blood in the pulmonary capillaries; and internal respiration, the gas exchange

between the capillaries and tissue. The respiratory system involves pulmonary ventilation and external respiration. The respiratory system can be separated into two anatomical regions, the upper and lower airways. The upper airway is the region of the respiratory system between the nasal vestibules and the entrance to the trachea. This region is responsible for filtering, heating and humidifying the air, and the lower airway is the region between the trachea and the bronchioles, which provides a passage for the air to enter the alveoli. The respiratory tract is shown in Figure 2.

Figure 2. Human respiratory system. Adapted from Tortora and Derrickson (2011).

During inspiration, atmospheric air enters the nasal cavity via the nose, and the oral cavity via the mouth, if the mouth is open. The two cavities are separated by a septum called the palate. As the air passes the nasal vestibule, it is filtered by the vibrissae. In the nasal cavity, air is distributed through the turbinates, which heat and humidify the air due to their large surface area. At the posterior end of the nasal cavity is the nasopharynx, which is the most superior region of the pharynx. Air passes through the nasopharynx and velopharynx and will meet with the orally inspired air at the oropharynx. The air will then proceed via the laryngopharynx and the larynx. Ingested food and drink also pass through the oropharynx and laryngopharynx before entering the esophagus. The epiglottis, a cartilaginous flap-like extension, is located at the posterior base of the tongue, and will close off the airway during swallowing to prevent any bolus from entering the lower airway. Air enters into the lower airway via the larynx, which is the interface between the trachea and the pharynx. The larynx is also the site of the vocal folds, which are a pair of tissue folds with the primary function of voice production. An illustration of the upper airway is shown in Figure 3.

Figure 3. Anatomy of the upper airway. Image created by the author.

The lower airways provide passage to the alveoli where external respiration takes place. The air passes down the trachea, a 100 - 110 mm long tube of diameter 15 - 20 mm (Gray, 2009), which is reinforced with C-shaped cartilage rings, to prevent from collapse. The trachea eventually bifurcates into two primary bronchi, which lead to each lung and further bifurcate into bronchioles for approximately 20-23 generations (Weibel, 1989). At the end of each bronchiole are the alveoli ducts, which is the site of external respiration. Each duct consist of alveolar sacs, which are comprised of at least 2 alveoli that share a common opening. Gas exchange between the blood capillaries and the alveolar sac occurs by diffusion via the respiratory membrane. The upper airway, trachea, bronchi and bronchioles are often referred to as the conducting zone of the airway, as no gas exchange occurs in these regions of the respiratory tract and the alveolar ducts are often referred to as the respiratory zone as this is the site of gas exchange.

2.2 Spirometry

Air is inhaled due to the contraction of the intercostal and diaphragm muscles, which cause the thoracic cavity to expand in volume; this results in a negative pressure and drives air flow into the lungs. Because work is done by

the muscles, inhalation is an active process. In contrast, exhalation occurs as the respiratory muscles relax and recoil due to their natural elasticity, and hence this makes exhalation a passive process. The respiratory rate (RR) is the frequency of breaths carried out in one minute, and in a healthy adult, this corresponds to approximately 12 breaths per minute (inhaling and exhaling). Approximately 500 mL of air is drawn during one breath and this is referred to as the tidal volume (TV). Minute ventilation (MV) is a measure of how much air is inhaled and exhaled in one minute, and for the same example, this equates to 6 L/min. Minute ventilation does not measure the amount of gas exchanged during respiration. From the 500 mL of tidal volume, only 350 mL reaches the respiratory zone, where gas exchange takes place. The remaining 150 mL remains in the nose, pharynx, larynx, trachea and bronchi (conducting zone) and is referred to as the anatomical dead space. If a healthy adult inhaled as much air as they possibly could, an extra 3100 mL could be achieved after tidal volume for men, and 1900 mL could be achieved for women; this is referred to as the inspiratory reserve volume (IRV). Functional residual capacity (FRC) is the volume of air that remains in the lungs after a passive exhalation and corresponds to 2400 mL for men, and 1800 mL for women. After a normal exhale, if air was forcibly further exhaled, men could expel 1200 mL of air, and women could expel 700 mL. There would still be air remaining which cannot be exhaled, as it is required to keep the alveoli inflated. This is referred to as the residual volume (RV) and corresponds to 1200 mL for men and 1100 mL for women. The total average lung capacity for adults is 6000 mL for men and 4200 mL for women. Figure 4 summarises the lung capacities in men and women.

Figure 4. Lung volumes in adult humans. The capacities in brackets correspond to female physiology. Image created by the author.

2.3 Soft Tissues in the Airway

2.3.1 The Tongue and Soft Palate

Soft Palate

The soft palate forms the posterior end of the roof of the mouth. It is an arch shaped muscular extension and starts from the posterior end of the hard palate, and ends near the velopharynx. The inferior most end of the soft palate is the uvula, which hangs above the oropharynx. The soft palate and the hard palate form a wall that separates the oral and nasal cavities and make it possible to chew and breathe simultaneously. The soft palate is often implicated in obstructive sleep apnea (OSA) syndrome, as the collapse of this tissue can occlude the flow of air. The soft palate is illustrated in Figure 5.

Figure 5. The soft palate structure and location. Adapted from www.headandneckcancerguid.org

Tongue

The tongue is a muscular hydrostat and an accessory digestive organ. It is composed of skeletal muscle and covered in mucous membrane. The tongue forms the floor of the oral cavity. It is made up of 8 muscles- four are intrinsic and four are extrinsic. The tongue is divided into two lateral halves by a median septum and each half contains identical intrinsic and extrinsic muscles. The anatomy of the tongue is shown in Figure 6.

Figure 6. Anatomy of the human tongue. Adapted from Drake et al. (2009)

The extrinsic muscles originate outside of the tongue and insert into it. These muscles move the tongue posteriorly, anteriorly and laterally to manipulate food. The four extrinsic muscles are: genioglossus, which depresses and protrudes the tongue, it also constricts its motion to prevent it from occluding the airflow and the relaxation of this muscle is associated with obstructive sleep apnea; the hyoglossus depresses and retracts the tongue; syloglossus muscle retracts the tongue; and the palatoglossus muscle elevates the posterior tongue. The intrinsic muscles exist within the tongue and are responsible for altering the shape and size of the tongue for speech and swallowing. These include the longitudinalis muscle, which raises the tip and sides, it also shortens the tongue; the longitudinalis inferior muscle, which curls the tip in the inferior direction and shortens the tongue; the transversus linguae muscle narrows and lengthens tongue; and the verticalis linguae muscle flattens and broadens the tongue.

2.3.2 Vocal Folds

The vocal folds are a pair of tissue folds located in the larynx, and are responsible for voice production in humans. The larynx is anterior to the esophagus and is the interface between the upper and lower airways as it is inferior to the laryngopharynx and superior to the trachea. A frontal cross section of the larynx is shown in Figure 7 (left). The structure of the larynx is composed of 9 pieces of rigid cartilage, which consist of 3 single cartilages - thyroid, epiglottis and cricoid; and 3 cartilage pairs known as the arytenoid, cuneiform and corniculate cartilages. The arytenoid cartilages are the most significant regarding voice production, as their movement manipulates the position and tension of the vocal folds, ultimately changing the pitch produced. The vocal folds abduct during voice production, resulting in closure of the aperture between them, known as the rima glottidis. During normal breathing, the area of the rima glottidis can range from person to person between 131 mm² to 239 mm² (Rubinstein et al., 1989). Other structures located in the larynx include a pair of folds called the vestibular folds (false vocal cords), which consist of pairs of ligaments, with superficial layers of mucosal membranes and are located superior

to the vocal folds. They do not contribute to voice production, but their function involves pressure modulation of the thoracic cavity when holding the breath, by contracting and hence closing the air way.

Figure 7. Frontal cross-section of the larynx (left), axial view of the vocal folds, as would be seen with a laryngoscope (right). Adapted from Tortora and Derrickson (2011).

The vocal folds are comprised of multiple layers and this histology is shown in Figure 8. The most superficial layer is the epithelium and directly underneath is the superficial lamina propria. These two tissues form the vocal fold mucosa, or often referred to as the vocal fold cover, and this moves freely during phonation due to vibrations. The deeper layers are comprised of connective tissue and are called the intermediate and deep lamina propria; these form the vocal ligament and have a greater stiffness compared to the vocal fold mucosa. The deepest layer is the vocalis muscle. Each vocal fold is approximately 12 -24 mm in length and has a total thickness of 3 -5 mm (Hahn et al., 2006). The vocal folds stretch out across the rigid cartilages of the larynx, with one end of each band connected to respective arytenoid cartilage and the opposite ends meeting in the middle of the thyroid cartilage, which acts as the pivot for the ligament pair (Tortora & Derrickson, 2011).

Figure 8. Coronal cross-section of a single vocal fold showing the histology. Adapted from Rosen et al. (2008)

There are several muscles associated with the movement and tension regulation of the vocal cords. Adduction of the vocal folds (folds closing together) is carried out by the lateral cricoarytenoid (LCA), thyroarytenoid (TA), interarytenoid (IA) and cricothyroid muscles. The TA muscle consists of two main bellies- the internus and the externus bellies. During contraction, the externus portion causes the vocal ligaments to thicken, and results in adduction of the airway. The internus portion causes the vocal folds to shorten and thicken, resulting in lower resonant frequencies. The TA muscle is also referred to as the vocalis muscle and is situated in the mucosal membrane, running in parallel with the vocal ligament. The cricothyroid muscle causes the vocal ligaments to tighten and stretch, resulting in a higher resonant frequencies and hence higher pitch during phonation. The cricothyroid muscle is the only muscle that creates tension in the vocal folds. The posterior cricoarytenoid (PCA) is the only muscle pair responsible for abduction (moving vocal folds apart). The diagram in Figure 9 illustrates the muscles and connective tissue located in the larynx.

Figure 9. Axial view of the connective and muscular tissue located in the larynx. Adapted from Gray (2009)

The production of sound in the larynx is a complex function and has been studied over the years resulting in many theories on phonation. Phonation refers to the production of sound due to the periodic vibration of the vocal folds. One theory on phonation is the body-cover concept, and explains that a wave like motion occurs in the vocal fold cover. This process starts with inhalation and closure of the glottal space. Following the closure, the subglottic pressure builds up until it exceeds the force of the closed vocal folds. As air passes between the vocal folds and through the rima glottidis, vibrations will occur in the cover. Once expiration is complete, the vocal fold edges return to their resting position due to pressure drop and elastic recoil. The cycle is then repeated. There are a

number of conditions which voice production relies upon and these include: sufficient breath to produce the right amount of pressure in the subglottic region; control over the laryngeal muscles to establish the appropriate vocal fold length, tension and closure of the glottic space; and appropriate flexibility of the of tissues in the vocal folds (Rosen et al., 2008). The body-cover concept is demonstrated in Figure 10.

Figure 10. Coronal cross-section of the vocal folds illustrating the vibration of the tissues during phonation. Adapted from Rosen et al. (2008)

3 Literature Review

3.1 Airway Studies

3.1.1 Airway Modelling

The earliest methods of flow modelling in the airways involved *ex vivo* flow visualisations in the nasal passages of cadavers. One method that was carried out entailed the distribution of red litmus paper in the airway and pumping ammonia saturated air into the nasal cavity of a cadaver. Air flow was tracked by noting where the litmus paper turned blue (Paulsen, 1882). Other methods involved dividing a cadaveric head and replacing the septal wall with a glass plate. A problem with this is that it did not reproduce the joining of the two streams (left and right) at the pharynx. The first *in vitro* experiment was carried out by Proetz (1953) who created a cadaver-based cast model of the nasal cavity for reusability. Proetz (1953) concluded that there is a typical pattern of the air flow during breathing, but it is also dependent on the anatomy specific to the individual. Other *in vitro* visualisation experiments include the study by Simmen et al. (1999) who used physiologic breathing cycles rather than the steady flow velocities used in previous studies. The studies by Proetz (1953) and Simmen et al. (1999) used smoke-laden air for flow visualisation which was difficult to image. Further studies have utilised dye in water filled models to track the streamlines (Weinhold & Mlynski, 2004).

Although flow visualisation is a robust way to investigate nasal air flow patterns, it provides qualitative results, and hence it is difficult to compare and analyse with other studies. Modern experiments have employed more advanced *in vitro* techniques resulting in physical measurements of flow characteristics in the nasal airway. Accurate nasal airway geometries can be modelled using of magnetic resonance imaging (MRI) and computed tomography (CT) scan images. Hahn et al. (1993) conducted a study using a 20x scale right half adult nasal model based on medical imaging. They used hot wire anemometry to assess airflow when administering steady flow rates of 0.6, 10.8, 33.6 and 66 L/min. They determined that air flows ranged from disturbed laminar to turbulent as the flow rates increased. In recent years, the emerging technology of 3D printing has allowed accurate fabrication of medical image based, anatomically correct upper airway models. Recent studies have used such models to perform static pressure testing and capnography at various points along the airway (Adams et al., 2016; Dey, 2014; Van Hove et al., 2016). The airway models had been specially designed with pressure taps along regions of the pharynx to allow for pressure and capnography measurements. Particle image velocimetry (PIV) has been used as a more advanced method of flow visualization, and has allowed mapping of the air velocity throughout the airway. In the past, PIV studies investigated steady flows on one side of the upper airway (Hörschler et al., 2006; Kelly et al., 2000; Kook Kim et al., 2006; Park et al., 1997). More recently, PIV studies were carried out on complete upper

airway models and simulated natural and nasal high flow assisted breathing using both steady and oscillatory flows (Spence et al., 2012; Spence et al., 2011; Spence et al., 2010).

The constant progression in computing technology has increased the power of computational fluid dynamics (CFD) which has proven to be a useful method to investigate nasal air flow patterns. It is a feasible option as it is non-invasive, relatively quick, and a cheap method to study the complicated flow pattern in the airway. The studies are almost exclusively carried out on simplified medical image based geometric models with steady flow conditions (Hörschler et al., 2006; Jeong et al., 2007; Stringer et al., 2010). Previous CFD studies have simplified geometry by focussing on nares to nasopharynx (Hörschler et al., 2006; Ishikawa et al., 2006), one half along the sagittal plane (Gambaruto et al., 2009) or have modelled the full upper airway region (Jeong et al., 2007). Air flow simulations have been known to utilize Reynolds-averaged Navier-Stokes (RANS) settings (Ishikawa et al., 2006; Stringer et al., 2010; Taylor et al., 2010) and Large Eddy Simulations (LES) (Lee et al., 2010; Mylavarapu et al., 2009). The complicated geometry within the nasal cavity requires a high density mesh to accurately simulate the flow, and this has restricted the application of Direct Numerical Simulations (DNS) for upper airway flow simulations.

3.1.2 Nasal High Flow Therapy

The nasal cannula was invented by Wilfred Jones in 1949 and is a method of delivering supplementary oxygen for patients with respiratory difficulty. The nasal cannula originally administered cold, dry gas and was limited to delivering at flow rates between 1-6 L/min. High flow rates of unconditioned air is prone to irritating and damaging the internal tissue of the nasal cavity as it would dry out the nasal mucosa (Campbell et al., 1988). Humidified respiratory therapy was invented by Dr Matt Spence at Auckland hospital in the 1960s, and brought to the market by Fisher and Paykel Ltd. This began the introduction of nasal high flow therapy (NHFT) as a mode for non-invasive ventilation and involves delivery of air at relatively high flow rates via the nasal cannula. High flow rates between 10 – 60 L/min can be delivered to adults and up to 12 L/min for infants, because the air is heated to 37°C and humidified to 100 % relative humidity, which is tolerable by the body. Dysart et al. (2009) proposed that NHFT has five mechanisms that contribute to its efficacy. These are the washout of nasopharyngeal dead space, reduction of inspiratory resistance and improved lung mechanics through the supply of adequately warmed and humidified gas, reduction in the metabolic cost of gas conditioning, and provision of distending pressure.

As explained previously (Chapter 2, section 2.2), anatomical dead space is the volume of air which remains in the conducting zone of the airway after expiration, and is rebreathed on inspiration. Anatomical dead space contains ‘stale’ CO₂ rich gas at similar concentrations to the alveoli (Tortora & Derrickson, 2011). NHFT can increase the efficiency of respiration as the washout mechanism can flush CO₂ gas; this can improve alveolar ventilation by

increasing its proportion with respect to minute ventilation, hence increasing oxygenation (Dysart et al., 2009). Chatila et al. (2004) compared the effects of low flow oxygen (LFO) and high flow oxygen (HFO) therapy in COPD affected patients. They found that patients that HFO had higher oxygenation and could exercise longer. Similarly, Dewan and Bell (1994) compared HFO and LFO, and administered the therapy via a nasal cannula and transtracheal catheter (TTC) in COPD effected patients. They agreed with Chatila et al. (2004), that HFO therapy significantly increased the exercise tolerance of the patients compared to LFO therapy. Adams et al. (2016) performed capnography experiments on a benchtop upper airway model to investigate the washout mechanism of NHFT. They used a closed mouth airway and replicated the oscillatory flow of respiration by using a pump that was programmed by a Fourier waveform that was faithful to the physiological breath pattern. They measured CO₂ concentration at the tracheal entrance of the upper airway and found that NHFT reduced the CO₂ concentration by 17 % and 24 % for 30 L/min and 60 L/min therapy flow rates, respectively. Van Hove et al. (2016) also studied the washout mechanism using a computational approach on a 3D, closed mouth, airway model, and validated it with *in vitro* experimentation, identical to Adams et al. (2016). During natural breathing, it was found that the CO₂ concentration throughout the upper airway was approximately 5 % volume fraction which is similar to the CO₂ concentration in the alveoli. With the application of NHFT, the anterior portion of the nasal cavity had much lower CO₂ concentrations. This region of low CO₂ concentrations would extend posteriorly with higher therapy flows, as the cannula jet would penetrate further in the nasal cavity. With the application of 60 L/min NHFT, the CO₂ concentrations in the pharynx reduced up to 4.4 % volume fraction and when comparing natural breathing, and with NHFT at 60 L/min, the volume of inspired CO₂ gas decreased by 65 %. However, the effects of washout would plateau with flow rates of 40 L/min and greater. They mentioned that CO₂ rich air escaped via the nostrils reducing anatomical dead space due to circulation features caused by the cannula jet on expiration. This was also noted by Spence et al. (2012) who used PIV to investigate the flow pattern in an upper airway models for both natural and NHFT assisted breathing. Spence et al. (2012) observed recirculation regions above and below the cannula jet during NHFT, and found that this continuously flushed the dead space in the nasopharynx.

The second mechanism proposed by Dysart et al. (2009) is that NHFT reduces the work of breathing (WOB). Work of breathing describes the body's effort to inhale and exhale air for respiration. Currently, there are no publications of the mechanism in adults as the studies have been limited to children and infants. Rubin et al. (2014) studied the effects of NHFT on WOB in small children. They measured the respiratory rate, and the esophageal pressure, which acted as a surrogate for pleural pressure, on paediatric ICU patients with administered therapy flows of 2, 5 and 8 L/min. They quantified the WOB with pressure rate product (PRP), which was calculated by multiplying the change in pleural pressure by respiratory rate. They found that PRP would decrease with increasing therapy flows with an approximate reduction of 25 % when therapy flow rate increased from 2 to 8 L/min flows. It is likely that the reduction in PRP was partly due to the other mechanisms, such as the generation in positive

airway pressure and dead space washout. However, they found that the baseline pleural pressure, the pressure measured at the end of an exhalation, increased by 1 cm H₂O between 2 and 8 L/min therapy flows, which was not significant enough to be fully responsible for the 25 % PRP decrement. Pham et al. (2015) investigated the WOB on infants with bronchiolitis and post-cardiac surgery infants. They measured PRP, pressure time product (PTP) during inspiration, and the peak electrical activity of the diaphragm (Edi_{max}) with administered NHFT at 2 L/kg/min for each infant. The PTP during inspiration was defined as the integral of the esophageal pressure curve during the inspiratory phase. With no therapy, Edi_{max} was greater in bronchiolitis affected infants, and in cardiac infants this resembled a normal range, indicating that they showed no clinical signs of increased WOB. However, with NHFT, the Edi_{max} decreased for both infant groups. It should be noted that reduction in Edi_{max} did not take into account reduction in RR on NHFT. The PRP and PTP was shown to reduce by 38 % and 44 % for bronchiolitis affected infants, respectively; and for cardiac infants, this reduced by 35 % and 34 % respectively. Hence NHFT reduced the WOB breathing on both infant groups, with more pronounced effects on the bronchiolitis affected group.

Dysart et al. (2009) proposed that NHFT improves pulmonary conductance, compared to cold, dry gases. To date, there are no such publications which have explicitly investigated this mechanism. However, this mechanism has been implied by studies which have shown that when breathing cold, dry gas, the body induces a bronchoconstriction as a protective response in both normal and asthmatic patients (Fontanari et al., 1996; Fontanari et al., 1997).

During respiration, air must be heated and humidified in the conducting zone of the respiratory tract, and hence there must be some associated energy expenditure in the generation of heat and mucus in the internal airway surface. Because the air from NHFT is already conditioned it is more tolerable for the body, and hence this would contribute to the reduction in WOB; however, it has been shown that the conditioning of the air is more important for patient comfort and mucosal secretion clearance, rather than caloric expenditure. NHFT studies report a decrease in nose, throat and mouth dryness due to improvement in upper airway mucosa dryness compared to conventional oxygen therapy (Cuquemelle et al., 2012; Nava & Hill, 2009; Roca et al., 2010; Sztrymf et al., 2011). In disorders such as COPD and bronchiectasis, which impair mucociliary transport, and cause mucus retention, NHFT has been shown to improve mucociliary clearance (Hasani et al., 2008; Rea et al., 2010).

The fifth mechanism of NHFT proposed by Dysart et al. (2009) suggests that elevated pressures are achieved. Continuous positive airway pressure (CPAP) is a method to maintain an open passage for breathing. It was originally intended to treat obstructive sleep apnoea (OSA), as the positive air pressure in the pharynx prevents the collapse of the soft palate. However, CPAP has been used to assist ventilation as the positive pressure increases

alveolar recruitment in patients with respiratory failure, allowing for more gaseous exchange to take place. There have been a number of *in vivo* experiments that support the fifth mechanism proposed by Dysart et al. (2009) (Groves & Tobin, 2007; Parke et al., 2011; Ritchie et al., 2011). Groves and Tobin (2007) measured the expiratory and inspiratory pressures at the pharynx for both mouth open and closed breathing in 10 adult subjects, with intranasal flow rates between 0 – 60 L/min. It was found that pharyngeal pressures would increase with flow rates, and mouth closed breathing resulted in greater pressures compared to mouth open. For a nasal flow rate of 40 L/min for mouth open and mouth closed breathing, the end expiratory pressures were found to be 2.2 and 5 cm H₂O in male subjects, respectively. This result agrees with intrinsic positive end expiratory pressure. The women subjects exhibited greater pressures than the male subjects, which is thought to be due to their smaller nasal geometries. Ritchie et al. (2011) and Parke et al. (2011a) conducted similar experiments with healthy volunteers and post cardiac surgery patients, respectively. Ritchie et al. (2011) obtained expiratory pressures that agreed with Groves et al. (2007) and concluded that there is a linear relationship between increasing flowrate and increasing pressures in the upper airway. Parke et al. (2011a) recorded pressures in the nasopharynx and these were found to be approximately half of Groves et al. (2007). Difference in results may have been due to the difference in catheter locations in the subjects, and due to specific differences in nasal geometries. However all three studies agreed with the correlation between nasal flow rates and pressures in the air way.

3.2 Tissue Properties

3.2.1 Soft Palate and Tongue

There have been several studies that have investigated the mechanical properties of the soft palate and tongue. These involve estimation from numerical modelling; *ex vivo* testing on excised tissues from animals or cadavers; and *in vivo* testing. In a study performed by Cheng et al. (2011), magnetic resonance elastography (MRE) was carried out as a means of obtaining viscoelastic properties of the tongue and soft palate. Cheng et al. (2011) measured the shear modulus of the tongue and soft palate to be 2.7 ± 0.3 kPa and 2.5 ± 0.3 kPa (mean \pm SD), respectively. Malhotra et al. (2002) studied pharyngeal collapse tendencies in during OSA, by monitoring anatomic and pathophysiological features of the upper airway in healthy subjects. They performed standard polysomnography and magnetic resonance imaging (MRI) and developed a finite element (FE) model of the airway using the signal averaged anatomic data. They used reverse algorithms to determine the mechanical properties of tongue and soft palate based on the motions and exerted pressure. The FE model was simplified by assuming uniform stiffness throughout the entire region. During a sleeping condition the elastic modulus for the tongue and soft palate was 12.4 kPa and for a paralyzed condition with no muscle activation, it was 6 kPa. Xu et al. (2005) also used an MRI based FE model to calculate the elastic modulus of the tongue and soft palate. Their value of 5 kPa for soft palate, agreed with Malhotra et al. (2002), and but the 3.5 kPa they calculated for the tongue

did not. However the study by Xu et al. (2005) was performed on the airway of a rat, and can explain the discrepancy when comparing to the aforementioned studies. Berry et al. (1999), also developed a FE model of the soft palate. Their model had 11 layers in the anterior-posterior direction and 3 layers in the superior-inferior direction. Each anterior-posterior layer was assigned a different elastic modulus, according to the histology of the soft palate and the assigned elastic modulus values were based from known values of different biological tissue types reported by Ettema and Kuehn (1994). The elastic modulus of the FE model was measured and found to range from 100 kPa at the attachment of the hard palate and 0.51 kPa at the most posterior region. Birch and Srodon (2009) performed *ex vivo* experiments on 10 whole adult soft palates from cadavers aged 37 – 90 years. Stress-relaxation methods were used to determine the stiffness of 10 different anatomic regions of the soft palate. The elastic modulus was found to be 0.585 kPa at the uvula region to 1.41 kPa at the hard palate attachments. The stiffness at the uvula found by Birch et al. (2009) matched that of Berry et al. (1999), however the stiffness at the hard palate attachment was significantly lower. It should be noted that there can be difficulty in determining mechanical properties of biological tissues with *ex vivo* experiments as the tissue is subject to change from post mortem effects (Garo et al., 2007). Properties can also vary in *in vivo* tissue due to muscle tone, hence they are rate dependent. The elastic modulus values for tongue and soft palate from the mentioned studies are summarised in Table 1. It should be noted that the shear modulus values from Cheng et al. (2011) were converted into elastic moduli by assuming the tissues were linear elastic, isotropic and homogeneous with a Poisson's ratio of 0.49, as per Zhu et al. (2012). This was to be able to compare the measurements by Cheng et al. (2011) directly to the other studies.

Table 1. Summary of reported elastic modulus values for the tongue and soft palate

Study	Elastic Modulus (kPa)		Method
	Tongue	Soft Palate	
Cheng et al. (2011)	7.74 ± 0.84	7.4 ± 0.9	<i>In vivo</i> MRE
Malhotra et al. (2002)	6	12.4	<i>In silico</i> Finite Element
Berry et al. (1999)	-	0.51 - 100	<i>In silico</i> Finite Element
Xu et al. (2005)	1.17	1.67	<i>In silico</i> Finite Element
Birch et al. (2009)	-	0.585- 1.41	<i>Ex vivo</i> Stress-relaxation

3.2.2 Vocal Fold Tissues

Alipour-Haghighi and Titze (1991) measured the elastic modulus of the vocal fold cover and the deeper vocal fold body of excised canine larynges. They employed a dynamic stress-strain method where sinusoidal, uniaxial stresses were applied at 0.5 to 10 Hz for strain ranges between 0 - 40%. The stress-strain response of the tissue

that they modelled was non-linear and exhibited hysteresis, which is typical for viscoelastic materials. However, Alipour –Haghighi et al. (1991) found that linearity was exhibited for small strains below 15 % and hence a hookean model could be used to describe the elasticity at this range. The low strain values were particularly of interest for their study as they represented the most normal phonation (Hollien, 1960). From the study, they found an average elastic modulus at low strains were $20.7 \text{ kPa} \pm 2.4 \text{ kPa}$ for the body and $41.9 \text{ kPa} \pm 7.1 \text{ kPa}$ for the cover which are significantly higher than the values from other studies. It should be noted that canine vocal folds do not have a vocal ligament, which is thought to contribute to a large portion of the stiffness for the deep layers and perhaps explains why their values do not match others. Chan et al. (2007) studied the tensile properties of human vocal fold cover (lamina propria) and ligaments. They used similar *ex vivo* testing methods as Alipour –Haghighi et al. (1991), with frequencies of 1 and 10 Hz. They also found linear behaviour under 15 % strain, and high non-linearity at strains greater than 40 %. Chan et al. (2007) found that at the non-linear portion, male vocal fold covers were approximately 2 times greater than female vocal fold covers and male vocal fold ligaments were approximately 3 to 5 times greater than female vocal fold ligaments. Kelleher et al. (2011) also employed a similar dynamic stress-strain method at 1 Hz cycles on excised human larynges. They reported a mean elastic modulus of 15.9 kPa and 13.9 kPa for the vocal fold cover, and vocal fold ligaments respectively. In their study, they also used optical methods to measure the strain for the applied stresses, for validation. With this method they measured a elastic modulus of 89.4 kPa and 61 kPa for the vocal fold cover and ligaments respectively. Tran et al. (1993) used *in vivo* techniques to measure the elastic modulus of the vocal folds on volunteers. They applied transcutaneous electrical nerve stimulation at different levels when measuring elastic modulus, to simulate muscle contraction. The *in vivo* studies treated the vocal folds as one homogeneous component, however as mentioned previously, the histology of the vocal folds involves multiple layers of tissues with different rigidities. Tran et al. (1993) found a mean elastic modulus of 12.7 kPa which closely resembled the values for vocal fold cover and vocal ligament measured by Kelleher et al (2011). Chhetri et al. (2011) measured the elastic modulus for four different layers of the vocal folds. They carried out the testing with the indentation method and Hertzian contact theory. The method was validated by measuring the elastic modulus of silicone composites with known mechanical properties. They performed tests on the inferior medial surface of vocal fold cover, medial surface of cover, superior surface of vocal cover and the thyroarytenoid muscle. The mean elastic modulus was calculated to be 8.6kPa, 7.5kPa, 4.8kPa, 2.9kPa and 2kPa, respectively. Chhetri et al. (2011) also estimated a Poisson's ratio of 0.47 for the Hertzian model. The reported values of vocal fold elastic modulus are summarised in Table 2.

Table 2. Reported elastic moduli for the vocal folds from different studies

Study	Elastic Modulus	Method
Alipouri-Haghighi et al. (1991)	41.9 kPa (cover) 20.7 kPa (Body)	<i>Ex vivo</i> (canine) Dynamic stress-strain
Tran et al. (1992)	12.7 kPa	<i>In vivo</i> Strss-strain
Kelleher et al. (2011)	16.1 kPa and 89 kPa (cover) 17.6 kPa and 61 kPa (ligament)	<i>Ex vivo</i> Dynamic stress-strain
Chhetri et al. (2011)	2 kPa - 8.6 kPa	<i>Ex vivo</i> Indentation
Chan et al. (2007)	4.7 kPa – 6.7 kPa (ligament), 8.1 kPa - 14.9 kPa (cover)	<i>Ex vivo</i> Dynamic stress-strain

3.3 Studies in Compliance

3.3.1 Compliant Soft Palate Airway Condition

There have been several past studies that have investigated how soft palate compliance affects breathing. These have all been limited to computational studies which use fluid-structure interaction (FSI) methods. Studies have been exclusive to natural breathing conditions with a closed mouth airway.

Pirnar et al. (2015) carried out an FSI study on an upper airway model based on CT image data. They investigated the collapse of pharyngeal tissues implicated by OSA, and simulated soft palate compliance by assigning a realistic, previously reported elastic modulus to the tissue region (Cheng et al., 2011). On inspiration, the greatest negative pressure occurred in the velopharynx, which was the narrowest section. The force from the negative static pressure caused the soft palate to tend toward the posterior direction, reducing the cross-sectional area by 10 %, and causing a more negative pressure in the region (Bernoulli's law). On expiration the positive pressure in the velopharynx exerted a force on the soft palate, causing it to move toward the anterior and increasing the velopharyngeal cross-sectional area by 4 %. They compared the FSI studies to CFD simulation, which assumed a completely rigid airway condition. At the peak inspiratory phase the compliant airway experienced a net airway pressure of -44 Pa, and the rigid experienced – 39 Pa. At peak expiration, the FSI simulation predicted a net airway pressure approximately 45 Pa whereas the CFD results predicted approximately 48 Pa. They also found that the soft palate would vibrate at approximately 17.8 Hz which was consistent with snoring frequencies found by Osborne et al. (1999).

Zhu et al. (2012) performed similar FSI studies on an airway with a compliant soft palate to also investigate mechanisms of OSA. Their study agreed with Pirnar et al (2015) that soft palate motion was caused by the exerted force from the pressure static pressure as opposed to the shear force. Contrary to Pirnar et al (2015), the soft palate tended toward the posterior on expiration, causing a narrowing of the velopharynx, and on inspiration the motion was insignificant. They measured static pressures in the nasopharynx and oropharynx and found that at peak inspiration compliant pressures were both approximately -28 Pa, which was lower than the -19 Pa measured in the rigid airway. At peak expiration, the pressures of the compliant airway were approximately 18 Pa which was lower than the rigid pressures of 21 Pa. The values of the peak pressures did not match between Pirnar et al. (2015) and Zhu et al. (2012), however the observed trends in pressures between compliant and rigid pressures were consistent. This may be attributed to difference in airway geometry and flow patterns as Pirnar et al. (2015) used a sinusoidal breath pattern with 25 L/min at peak inspiration and expiration, whereas Zhu et al. (2012) used a similar pattern with smaller peak flow rates of 7.5 L/min. Greater flow rates will correspond to greater airway pressures, also different airways will have different shape which can also effect the pressure losses.

3.3.2 Compliant Tongue

There have been a number of studies which investigated the flow-induced collapse of the tongue during OSA conditions (Chouly et al., 2008; Chouly et al., 2009; Liu et al., 2010; Rasani et al., 2011). These studies have used numerical FSI and *in vitro* experimental methods on a simplified airway model. The airway model comprised of a rigid pipe that corresponded to the pharynx of the airway and an intersecting cylinder, which formed a convergent-divergent passage and represented the tongue. This cylinder was made from either a rigid material, or deformable latex filled with water to replicate a compliant tongue. The diagram in Figure 11 illustrates the setup used in the study by Chouly et al. (2009).

Figure 11. *In vitro* airway model to replicate a compliant tongue condition. Adapted from Chouly et al. (2009).

The studies used a steady flow to simulate expiration, only and the compliance of the tongue was simulated by using an elastic modulus of approximately 1.6 MPa. The clearance between the tongue and airway wall (h_c) represented the smallest anterior-posterior distance at the oropharynx. This remained at 1.84 mm and was representative of the anterior-posterior distance at oropharynx in a sleep condition, which usually ranges between 1 – 2 mm (Chouly et al., 2006) . The narrowing of the constriction increased the transmural pressure due to the venturi effect. This induced a downwards deformation of the compliant tongue, causing subsequent narrowing. Comparing both rigid and compliant tongue conditions, the compliant airway had a greater resistance. Rasani et al. (2011) carried out an FSI study with a simplified model similar to Chouly et al. (2009). They tested with a range of different constriction heights from 0.8 - 11 mm, and also a range of elastic moduli from 1.25 to 2.25 MPa. They found that reducing the elastic modulus (hence increasing compliance), increased the collapsibility of the compliant tongue and hence increased the airway resistance. They also found that both the elastic modulus and the height of constriction are important parameters which affect the collapsibility of the tongue. At a constriction height of 11 mm, which was representative of a healthy, awake airway (Sforza et al., 2000), they found minimal deformations to the compliant tongue and the airway resistance resembled that of a rigid condition.

3.3.3 Compliant Vocal Folds

Many compliant vocal fold studies have focussed on phonation and have endeavoured to replicate self-oscillating models. The research in this thesis is interested in the effects of vocal fold compliance in normal breathing, and reported studies for this condition are limited. Kim et al. (2010) carried out a FSI study on a completely compliant, closed mouth airway which included nasal cavity, pharynx, larynx and trachea. The entire domain was modelled as compliant by assigning realistic elastic modulus values to the different airway regions. They used an elastic modulus of 4.9 kPa for the larynx which was based on pig tissue (Li et al., 2006). They found that the surface would deform by 0.9 mm. They only simulated inspiration in their study, with a peak inspiratory flow rate of 35.4 L/min. The larynx experienced the most negative pressures, reaching -85 Pa at peak inspiration. The larynx also experience the most significant deformation in the airway which was up to approximately 0.9 mm at peak inspiration, and was 10 times larger than the deformation of the trachea and the nasal cavity. This can be attributed to the large force exerted by the static pressure in the larynx, however this was also due to the relatively low elastic modulus of the larynx. Kim et al (2010) did not compare their studies to a rigid condition, and did not report how compliance affected respiration.

Gaon et al. (1999) studied the effect of nasal continuous positive airway pressure (CPAP) therapy on preterm infants, which is typically used to tackle apnoea caused by prematurity. They administered a CPAP level of 5 cm H₂O and they assessed the laryngeal cross-sectional area using fibroscopic imaging. It was found that with the application of CPAP, the width to length ratio of the larynx increased in the subjects by 12.5 % to 47 %. They

hypothesised that the changes in the glottis were either due to the CPAP stimulating the vocal fold abductor muscles, or due to the therapy's distending effects on the compliant larynx.

During respiration, there are involuntary muscle movements in the larynx, which cause small abductions and adductions, to modulate the air flow. During inspiration, there is a dilation of the cross-sectional area in the larynx reduces the airways' resistance to air flow. On expiration, a narrowing of the cross-sectional area in the larynx maintains the end-expiratory pressure in the lower airway and prevents alveoli collapse (Brancatisano et al., 1983; Shiba, 2010). Scheinherr et al. (2015) studied glottal area variation during respiration. They assessed the glottal motion in 20 volunteers (10 male, 10 female) using a nasal fiberscope, during different breathing tasks. They confirmed that the laryngeal cross-sectional area would increase on inspiration and decrease on expiration. They concluded that their subjects could be grouped into two categories, based on the extent of the glottal motion: static group and dynamic group. The static group corresponded to a glottal area change of less than 10 % between inspiration and expiration, and the dynamic group corresponded to glottal area change of over 10 %. The dynamic group reached a mean glottal variation of 24 % and 46 % during slow breathing, in males and females, respectively. In rapid breathing this corresponded to 24 % and 39 % in males and females respectively.

Previous studies in phonation have fabricated compliant vocal folds to investigate the acoustics of the larynx and the influence of air flow through the glottis. These models were often simplified, one-layered, homogeneous models. Most of these studies used the generic dimensions proposed by Scherer et al. (2001) to make vocal fold models with idealized geometries. Other simplifications include elastic, materially linear, and isotropic material properties, as opposed to viscoelastic, materially-nonlinear, anisotropic properties of human vocal fold tissue. Despite all these idealizations, these models have shown to vibrate at pressures and frequencies typical of human phonation (Pickup & Thomson, 2009). Thomson et al. (2005) used a self-oscillating model to explore transfer of aerodynamic energy from glottal airflow to the vocal folds. The vocal fold replica was a simplified one layer model portraying properties mentioned previously in the paragraph. The study aimed to replicate a vocal fold model that portrayed realistic characteristics which include onset pressure, oscillation frequency, geometry and material properties. The 3 part silicone solution that was used to cast the models had an elastic modulus of 13.7 kPa, similar to that proposed by Tran et al. (1993). The physical model designed by Thomson et al. (2005) has been used by several other similar studies that have investigated laryngeal aerodynamics and vocal fold vibration (Berry et al., 2006; Neubauer et al., 2007; Zhang et al., 2006a,b) and is depicted in Figure 12. In most mammals, vocal folds consist of at least two layers: a superficial vocal cover and a muscular body layer (Hirano & Kakita, 1985). Human vocal folds are known to also have a vocal ligament between the cover and the body. A level of sophistication has been implemented in other studies by using two-layered models to mimic the soft tissue cover layer and the stiff body layer of the vocal folds (Drechsel & Thomson, 2008; Riede et al., 2008). These models were adaptations of

the one-layered model made by Thomson et al. (2005) with similar manufacturing techniques to make a multi-layered models.

Figure 12. Vocal fold model adapted from Thomson et al. (2005)

4 Airway Model Development

4.1 Introduction

This chapter outlines the processes used to develop an anatomically correct airway model with soft compliant components. The airway model was based on a human adult male and extracted from computer tomography (CT) medical images using segmentation and mesh editing methods. The model was *in vivo* scaled (1:1 scale) and fabricated using 3D printing. The tongue, soft palate and vocal fold models were designed as removable inserts that could be adapted into the airway model. Two sets of these tissue models were made: a 3D printed rigid set, to simulate the original, rigid airway; and a silicone cast set, which replicated the compliance of the relevant tissues and could be used to simulate a compliant airway. The rigid and compliant insert sets were interchangeable and hence the same airway model could simulate a rigid or partially compliant boundary condition.

4.2 Digital Airway

4.2.1 Airway Geometry

Accurate airway models can be produced by using patient specific geometries based on computed tomography (CT) scan data. A CT scan uses x-ray imaging to capture a series of 2D cross-sectional images or ‘slices’ of a subject or patient body density across a single or multiple planes. X-ray images produce grey-scale images of body density with different tissue types distinguished by their pixel intensity. Image segmentation is the process of grouping pixels based on their intensity, which therefore can be used to identify the airway passages in the CT slices. An airway geometry was segmented from CT data by separating the airway passage from the surrounding tissue in each slice. This was carried out in the open source software 3D Slicer (www.slicer.org), where pixel intensity of the airway was specified by upper and lower limits, known as thresholding. In some cases, however, manual pixel selection was also required where tissue differentiation was poor and there was ambiguity between airway passage and internal tissue. Once the airway passage was selected in each slice, a 3D geometry was generated by the program by compiling each 2D selection and interpolating between the slices. The airway geometry used for this project was based on a CT scan of a 60 year old male. The CT scan captured a mouth open breathing condition. The CT scan data was imaged at 0.6 mm spacing between slices. Figure 13 shows a sagittal CT slice (left) and the extracted geometry from segmentation of the CT scan (right). It should be mentioned that for this project, a previously segmented airway was already provided. The procedures that were carried out by the author of this thesis begins in the following section (section 4.2.2).

Figure 13. A sagittal slice of a CT scan (left) and an extracted geometry (right)

4.2.2 Post processing Raw STL

Subsequent editing was required before the airway geometry could be used for 3D printing. The 3D digital model was in a stereolithography (STL) file format and was edited in Meshmixer (www.meshmixer.com) and Meshlab (www.meshlab.sourceforge.net) open source, mesh editing software. The mesh editing process involved the removal of features such as the paranasal sinuses, auditory tubes and tear ducts. These were extracted by the segmentation process, due to being within the threshold range, but not of interest to this study as there is no flow through them during respiration (Tortora & Derrickson, 2011). The trachea was also removed by truncating the geometry just below the larynx, as the upper airway was the main region of interest, and this would require additional material for printing. Although this had the potential to alter the development of physiological airflow, an artificial trachea was replicated with a tube of similar dimensions of a trachea, and connected to the airway during experiments (Brouns et al., 2006) (Chapter 5, section 5.7). The facial geometry was cropped to include a small portion around the nose and mouth region; this was required to cater for the nasal cannula and to preserve any local geometry around the facial outlet to simulate physiological conditions (Doorly et al., 2008). There was a large amount of streak artefact around the oral cavity, creating noise in the data. It is likely that this was due to the presence of metal fillings in the teeth, which have a density beyond the normal range of what is captured in x-ray imaging and thus causing scatter of the radiation (Figure 14). The artefact obscured and distorted the teeth and the internal surface of the oral cavity. The artefact was removed manually by deleting distorted regions, and using the smoothing tool in Meshmixer. This was a subjective process as it was difficult to discriminate between artefact and airway boundary. It was also difficult to completely preserve the geometry of the teeth, due to the extent of the artefact, however the resultant opening of the mouth maintained a superior-inferior clearance between 3 – 4.5 mm which was faithful to the original model. The edited STL airway geometry is shown in Figure 15.

Figure 14. Edited STL with streak artefact about the mouth region.

Figure 15. Airway STL with artefact removal and trachea truncation.

4.2.3 Processing STL into printable airway model.

At this point, the mesh was only a representation of the airway surface and only represented the negative airway passage. An outer surface was required to give the airway model volume and to produce a 3D printable, physical model. This was carried out by performing an extrusion of 2.5mm for the entire airway surface (Figure 16).

Figure 16. Airway shell after surface extrusion

At this stage, the digital airway model could be 3D printed. However, to fulfil the purpose for this project, several more design features were added to complete the model. These were as follows:

1. Clearing of soft tissue regions to create a cavity where these soft tissue components could be inserted and removed.
2. Adding female mating interfaces at the cleared tissue cavities. These were designed to allow for a press fit fastening between the airway and the insertable components. This will be explained further in the chapter (refer to section 4.2.4).
3. Separation of the airway model into two halves about the mid-sagittal plane. This provided access to the internal geometry of the airway and allowed for interchanging of the soft tissue components.
4. A flange was projected around the mid-sagittal plane. This provided more surface area and accommodated for size M4 screw clearances. The airway halves were fastened together with bolts.
5. A 38 mm diameter flange was extruded at the trachea end, with M4 screw clearances about a pitch circle diameter (PCD) of 33 mm. This allowed for attachment of external tubing, which would be connected to the pulsatile pump used in the experimental setup.

6. Pressure taps were incorporated at specific regions along the airway; these were essentially a cylindrical boss, with small holes that allowed for pressure probes to measure static pressures along the cavity, and the locations are summarised in Figure 17. The dimensions of the taps allow for accurate static pressure measurement and conform to findings by Shaw (1960). The design of the taps is shown in Figure 18.

The completed airway model is shown in Figure 19.

Figure 17. Map of pressure tap locations in the airway model. The numbers represent the taps, and the coloured lines correspond to their position on the airway. Red = left sagittal, orange = right sagittal and green = posterior or superior. The coloured airway sections correspond to the different regions in the upper airway.

Figure 18. Dimensions for the pressure ports along the airway

Figure 19. Digital model of completed airway. Grey and brown regions in the right image correspond to right and left halves, respectively.

4.2.4 Insert Design

Geometries for the soft palate, tongue and vocal folds were produced using similar segmentation methods, as described previously. Once they were extracted and rendered into STL files, design features were added to allow for the press fit interface with the airway model. Figure 20 shows one half of the airway model, which exposes the female mating interfaces for the removable soft component inserts. The airway model is designed to be dismantled for these inserts to be applied and removed from the model.

Figure 20. Airway half (grey) showing the tissue region cavities and the female mating interfaces (left), and airway showing soft palate (purple), tongue (brown) and vocal fold (green) inserts fitted into model (right).

Figure 21 shows the extracted soft palate with the anatomically correct geometry (left) and the added modifications for fitting into the airway (right). Figure 22 shows how the soft palate simulant was inserted into the airway model. The female mating region was essentially the negative of the soft palate; however, the dimensions for the mating regions of the soft palate component had to be reduced by 0.1 mm to compensate for any interference between the two components and to allow a proper fit. This interference was revealed by testing the quality of the fit with a 3D printed soft palate and a small region of the airway, local to the soft palate join (Figure 23). The 3D printing method will be described further in section 4.3.

Figure 21. Raw soft palate geometry (left) and a soft palate insert design (right). A boss was extruded on both sagittal sides of the soft palate body, following the contour of the soft palate shape. A stepped, 'T' shaped flange was extruded on top of the insert.

Figure 22. Soft palate insert (shown in purple) fitting into the airway (shown in grey).

Figure 23. Airway sample of left soft palate mating region (Left). Quality of join test for the soft palate insert (right)

The streaking artefacts present in the oral cavity also caused some distortion to the surface of the tongue. This created difficulty in extracting a complete tongue geometry, as a lot of information was lost due to the noise in the scan (Figure 24). The region of interest for the tongue is the surface that is exposed to air, to replicate the fluid-structure interaction. Although an entire tongue geometry could not be rendered due to the quality of CT data, the region of interest was mostly preserved. The geometry was truncated at both of its distal sagittal sides to remove most of the artefact. Any remaining noise in the region of interest was smoothed out in the mesh editing software. The process is shown in Figure 24.

Figure 24. Process of tongue extraction from CT scan (left), to raw 3D model (middle) to edited STL (right).

Similar to the soft palate insert, the tongue also required some design changes before it was complete for printing. This entailed making a more symmetrical model, particularly at the base where the shape was irregular. This was edited to a more symmetrical shape to allow an easier fit and to remove any potential interference. Figure 25 shows the changes made from the initial extracted STL, and the final digital tongue model. The changes were made to the mating region only, leaving the flow region unaffected. Figure 26 shows the tongue insert fitting into the airway.

Figure 25. Transition of tongue geometry (left) to a printable insert (right).

Figure 26. Depiction of how the tongue insert (brown) fits into the airway model (grey).

The vocal fold insert did not require any segmentation, as the geometry was already extracted from with the initial airway STL. The vocal folds were extracted by cropping the airway and leaving behind the larynx region. As mentioned previously, the model represented the negative space of the airway, and the external surface of the STL corresponded to the internal surface of the airway passage. The vocal fold insert was formed by building a symmetrical box-like structure around the original STL. A symmetrical design was required, as the irregular shape of the vocal folds would interfere with the airway region when trying to incorporate it into the model. Holes were added to all four walls of the vocal fold insert, and these aligned with the pressure taps in the airway model, and hence measurements could be taken at this region. The process of raw vocal folds to final digital model is depicted in Figure 27 and the Figure 28 shows the final vocal fold insert being adapted to the airway.

Figure 27. Raw vocal folds from raw airway model (left), final vocal fold insert (middle) and sagittal cross-section of insert illustrating the internal airway passage (left).

Figure 28. Vocal fold insert fitting into the airway model.

4.3 3D Printing of Rigid Components

4.3.1 Airway and Rigid Inserts

Printing of the airway model was carried out on a Projet HD 3000 Plus, photopolymer jetted 3D printer with a printing accuracy of 25 – 50 μm and layer thickness of 29 μm for a smooth finish. The printer used an acrylic printing material (Visijet EX200), and wax as the support material. These printing parameters were employed in similar in vitro airway studies (Dey, 2014). Alternative 3D printing considerations involved an Objet Connex, photopolymer jetted printer; and a Stratasys Elite, fused deposition modelling (FDM) printer with ABS plastic. The Objet Connex had similar properties to the Projet, with accuracies between 20 – 50 μm , and a layer thickness of 16 μm . The support material, however required water jetting, and there was no guarantee of complete removal from the airway model's complicated internal geometry. The Stratasys Elite printer was used for previous airway studies and although it was a cost effective method, undesirable properties were present in the resultant models, such as high surface roughness and low model resolution. Dey (2014) also reports post printing processes of the airway model, such as deburring the pressure taps, and application of multiple layers of PVA to seal any porosity that is inherent to the FDM printing method.

Rigid tongue and vocal fold tissue inserts were printed using the Projet printer in acrylic and the soft palate was printed by the Objet Connex in transparent plastic (VeroClear-RGD810). There was no important reason for this difference, other than equipment availability at the time of printing. Figure 29 shows the physical rigid inserts after printing. Figure 30 shows an airway half with inserts.

Figure 29. 3D printed rigid inserts. From left to right: Soft palate, tongue and larynx

Figure 30. 3D printed airway half with inserts

4.3.2 Realignment

Post printing it was observed that the airway halves had undergone warping and would not fit flush together, hence preventing correct alignment and proper assembling of the model (Figure 31). The support material removal phase of printing used heat to melt the wax, but consequently caused small distortions to the model. The heat induced distortions are generally negligible, however due to the relatively large size of the model, the length of time it took to remove all the support material resulted in noticeable deformation. The warping was remedied by heating the model to near its glass transition temperature and using thermal creep effects to realign the halves. The process involved assembling the model with the rigid inserts and loosely bolting together with care to avoid applying too much stress. The model was then heated to 65°C in a furnace, and the bolts were incrementally tightened every 45 – 60 minutes. The thermal creep effects allowed gradual realignment of the airway halves. The model was visually inspected at tightening intervals and was removed once satisfactory realignment was achieved. The model could not be aligned completely, particularly around the face, due to lack of bolt fixing holes. Clamps were used to apply more force during realignment, however the non-uniform surface of the facial geometry made it difficult to place force in the desired location. Post realignment, the model had a small clearance of approximately 3mm around the face, but this was limited to the tip of the nose. This was remedied by applying a seal to the model and will be explained in further in the chapter (refer to section Assembling and Sealing4.5).

Figure 31. 3D printed airway, pre-alignment

4.4 Compliant Insert Fabrication

4.4.1 Simulating Compliance

In physiology, compliance is the measure of an organs' tendency to recoil to its original dimension. To replicate tissue compliance, the tissue simulants must have similar mechanical properties as the corresponding *in vivo* biological tissues; however, this is difficult to achieve as there are many parameters to consider such as anisotropy, tissue histology, material non-linearity and viscoelasticity. Vegas and Martin del Yerro (2013) described compliance as the reciprocal of a tissues' elastic modulus. Previous studies that have investigated the fluid-structure interaction in a compliant airway simplified their compliant simulants by replicating the correct elastic modulus of the tissue, and made homogeneous and isotropic assumptions to maintain simplicity (Kim et al., 2010; Pirnar et al., 2015; Rasani et al., 2011; Zhu et al., 2012). In this study, a similar approach was carried out which involved fabricating the compliant tissues from a material which matched the elastic modulus. A summary of all the reported tissue elastic modulus values is shown in Table 3. For more detail refer to the literature review in Chapter 3, Section 3.2.

Table 3. Summary of tissue elasticity

Tissue	Reported elasticity range
Vocal folds	11 - 30 kPa
Soft Palate	0.51 - 7.5 kPa
Tongue	1.2 - 7.7 kPa

It was initially considered to 3D print the compliant inserts with soft materials which matched the elasticity of the relevant tissues. This was a convenient route as 3D printing is a rapid procedure and it would guarantee an

anatomically correct geometry. However comparing the tissue properties in Table 3 and the printing material properties in Table 4, it can be concluded that the 3D printing materials are not soft enough to achieve the desired properties.

Table 4. Summary of data for available flexible 3D printable materials

Material	Young's Modulus
Objet Tango™ materials	0.1-0.3 MPa
Duro®Form Flex	7.4 MPa
Formlabs FLFLGR02	~ 5.5MPa

An alternative solution was to use a polymer resin, which can be poured and cast in 3D printed moulds. The casting process for the compliant tissues is detailed in Chapter 4, Section 4.4.2. A previous study by Kashif et al. (2013) explored the elasticity of a RTV silicone resin (silicone A-341, Factor2 Inc.) with various mixing ratios of a thinning oil (50 cst, Dow Corning) to fabricate a polymer that reproduced the elasticity of breast tissue. The elasticities they found (Table 5) were in range of those summarised in Table 3, hence silicone A-341 was deemed as a suitable resin to fabricate the compliant tissues of interest for this study. The results by Kashif et al. (2013) can be interpolated to obtain the correct silicone and oil composition to produce the correct elastic modulus. It should be noted that Kashif et al. (2013) performed dynamic mechanical analysis (DMA) for their material tests, which applies sinusoidal stresses on a material to quantify the dynamic response. This is the conventional test method for viscoelastic materials such as biological tissues and soft polymers as it is able to quantify the complex modulus, which summarises both the storage (elastic) and loss (viscous) portions of the material. In their test, Kashif et al. (2013) used cyclic stress frequencies between 4 – 50 Hz, which was within the material's linear viscoelastic range, as the storage modulus was constant within this sweep.

Table 5. Summary of silicone A341 elasticity

Composition of A-341 (by weight)	Storage modulus (kPa)
100%	36
70%	21
50%	9.51
30%	2.1

The literature review in Chapter 3 Section 3.2 summarised the elastic properties for the soft palate, tongue and vocal folds from each reviewed study. There was a wide range of values reported with little agreement between each study, due to the various methods used. Although the reported studies did not explicitly perform DMA on the biological tissues, there were several which used dynamic techniques to quantify the elastic portion of the

viscoelastic parameter. For example, vocal fold studies performed a cyclic stress-strain tests (Alipour-Haghighi & Titze, 1991; Chan et al., 2007; Kelleher et al., 2011) and Cheng et al. (2011) measured the shear storage modulus of the tongue and soft palate directly with MRE methods. The elasticity values reported from the dynamic tests were shortlisted as potential compliance values for the study. From the shortlist, the smallest value of elastic modulus for each biological tissue was chosen to replicate the most compliant case. Table 6 summarises the chosen elastic modulus for each tissue, and the required silicone-thinning oil composition to achieve the corresponding elasticity.

Table 6. Selected tissue elasticity and the corresponding silicone A341 composition for compliance simulation

Tissue	Reported elasticity	Study	Silicone Composition (by weight)
Soft Palate	7.25 kPa	Cheng et al. (2011)	45.6 %
Tongue	7.83 kPa	Cheng et al. (2011)	46.4 %
Vocal Fold	4. 57 kPa	Chan et al. (2007)	38.8 %

Although Cheng et al. (2008) measured the shear storage modulus, this was converted to an elastic modulus using the relationship between elastic and shear modulus. Zhu et al. (2012) performed this conversion by assuming that the tissue is linear and isotropic. This is shown in the equation below, where G is the shear modulus, and ν is the Poisson's ratio, which can be assumed to be 0.45 (Birch & Srodon, 2009).

$$E = 2G(1 + \nu)$$

4.4.2 Casting Process

The compliant inserts comprised of two sub-components: a compliant body and a rigid frame. The compliant body encompassed the anatomical region where the fluid -structure interaction between air and tissue took place. This region was fabricated by casting into moulds with specific silicone mixtures (refer to section 4.4.1) and simulated the compliance of the tissue. The rigid frame was 3D printed and acted as the mating interface between the compliant insert and the airway model. The rigid frame also provided additional integrity to the compliant body, as deformations would occur due to the self-weight of the compliant structure. The complete compliant insert, with the combination of the compliant body and the rigid frame, was identical in geometry to its rigid counterpart.

Anatomically accurate moulds were 3D printed for casting the compliant body of the soft tissue simulants. These moulds were based on the same CT data as the rigid inserts, with further STL editing to create useable moulds. The digital 3D models of the tissues had to be adapted into negative versions of the geometries, with other added

features to make the casting process possible. The features included inlets for resin entry, outlets for any resin overflow and air removal, and brackets for holding during casting (Figure 32. Soft palate mould (top left), mould immersed in silicone resin (top right), tongue mould (bottom left) tongue mould immersed in silicone resin (bottom right)).

The moulds were printed in ABS plastic using FDM printing on the Stratasys Elite. The ABS material was desirable for its solubility in acetone as the moulds were designed to be sacrificial. Once the resin had cured, the cast extraction procedure took place and involved submersing the mould in acetone. This removed the ABS layer and left behind the silicone cast. A medium printing density was the optimum setting for mould printing; a low density resulted in a highly porous mould which increased risk of introducing unwanted air bubbles into the resin during casting; and a high density setting was unnecessary as it used more material and increased production cost for little benefit in the final product, relative to medium density.

Figure 32. Soft palate mould (top left), mould immersed in silicone resin (top right), tongue mould (bottom left) tongue mould immersed in silicone resin (bottom right).

The casting procedure used a bottom-up method, where the resin would enter from the bottom of the mould, similar to Geoghegan et al. (2012) . This method limited the inertial forces of the silicone resin and mitigated any mixing

with air. Air bubbles were unwanted as they had the tendency to attach to the walls of the mould and ultimately compromised the surface of the final cast. Outlets were added to the top of the moulds to allow for air to escape as the resin entered. Silicone A-341 was used as the material for casting the soft tissue simulants. The A-341 silicone was prepared by mixing a 10:1 ratio of parts A and B, by weight. Dow Corning 50 cst thinning oil was added to the mixture, with the amount depending on the soft tissue (refer to section 4.4.1) The casting procedure was carried out with the following steps:

1. The silicone resin was mixed and stirred in a small container.
2. The mixture was degassed in a vacuum chamber to remove any dissolved air. The degassing pressure was set to -80 inches Hg and the mixture was left in the chamber for 5 – 10 minutes.
3. After degassing, the moulds were slowly lowered into the resin filled container. The mould was lowered using tweezers or wire at the holding brackets. The silicone resin would enter the mould through the bottom inlets.
4. Once the moulds were completely immersed, they were left to cure for 4 hours.
5. After curing was complete, the moulds were carefully removed from the containers by cutting around the silicone at the wall of the container and sliding out. Silicone on the outer surface of the moulds was removed by hand.
6. The mould was immersed in a sealed beaker of acetone and left for 24 hours to dissolve the ABS surface.
7. Once all ABS material was clear from the silicone, the casts were removed and left in a fuming cupboard to remove any acetone residue. The resultant compliant casts for the tongue and soft palate are shown in Figure 33.

Figure 33. Compliant tongue (left) and soft palate (right) casts

The compliant tongue and soft palate bodies were cast in separate moulds and were fixed to their respective rigid frames after they were extracted, using a Sil-Poxy® silicone adhesive. The rigid frame of the tongue involved the square base and the walls of the insert. This was the area of the insert which was in contact with the airway region and hence acted as the mating interface. The compliant soft palate followed a similar design, where the rigid frame included the boss extrusions on the distal sagittal parts of the structure, and the top flange, as these were the mating regions (Figure 34).

Figure 34. The completed compliant tongue insert (left) and compliant soft palate insert (right)

The compliant vocal fold insert was modelled as a rigid frame with an internal compliant surface which contoured the shape of the laryngeal section of the airway passage. This compliant layer was 1- 3mm thick in the passage of the larynx, with the thickest portion around the vocal fold region corresponding to 2.5 – 3 mm. *In vivo* vocal folds are 3 -5 mm thick (Hahn et al., 2006), hence the silicone layer replicated the vocal fold cover and a portion of the vocal fold ligament. A diagram of the compliant vocal fold insert is shown in Figure 35.

Figure 35. Schematic of the complaint fold insert. Vocal fold insert with an intersecting coronal plane (left) and the corresponding, posterior coronal section view showing the internal compliant region (right).

The compliant vocal folds required a different casting process to work with its design. The rigid frame and the sacrificial ABS component were assembled together to form the mould. The rigid frame of compliant vocal fold insert was identical to the rigid insert, however the internal surface underwent an extruded cut by approximately 1 - 3 mm. This left a clearance on the internal surface to accommodate for the aforementioned compliant layer. Additional holes were added to the top of the insert, which served as an over flow outlet during casting. An internal ABS mould was inserted into the rigid frame and was used to form an anatomically correct laryngeal surface of the compliant layer. The combined rigid frame and internal mould formed the completed vocal fold mould. Figure 36 shows the mould arrangement for the compliant vocal fold insert.

Figure 36. Compliant vocal fold casting. The sacrificial internal mould (top left), the rigid frame (top right), the assembled mould (bottom left) and a bottom view of the mould (bottom right).

As with the tongue and soft palate casting process, the compliant vocal fold was also lowered into the silicone resin. The resin entered the 2.5 mm clearance between the ABS mould and the rigid frame and would overflow through the top outlets of the rigid frame, once it was completely immersed. After casting was complete, the mould was placed in an acetone bath, causing the internal ABS mould to dissolve and leaving behind the compliant vocal fold insert with an internal compliant surface which contoured the shape of the laryngeal section of the airway passage.

It is theorized that phonation occurs due to the body-cover concept, as described in Chapter 2 section 2.3.2. This describes that when the vocal folds are adducted, the flow across them causes the cover to vibrate. Although this project simulates a normal breathing condition, with open vocal folds, it was thought that the compliance of the vocal fold cover would have a significant influence on the air flow.

It could be seen that the resultant silicone casts had a greater surface roughness, compared to the corresponding rigid inserts. This is because, the FDM printing process, used for the mould fabrication, produces a rough surface finish on the ABS printing material, which directly impacts the cast. However, the surface roughness was remedied by applying a small layer of petroleum jelly onto the compliant cast.

It should be noted, that while the elastic modulus of the compliant tissue simulants may be realistic, the behaviour is a result of the elastic modulus and the boundaries with surrounding tissues. However, for simplicity, this study assumed that the compliant tissues were homogeneous and the surrounding tissues were assumed to be rigid. This is a limitation to the study.

4.5 Assembling and Sealing

4.5.1 Leak Testing and Gasket Selection

Sealing the airway model was required to prevent any leaks as these could contribute to error in pressure and flow measurements. In previous projects that used 3D printed airways (Dey, 2014), a non-setting gasket gel was used between airway parts; however the airway models in such projects remained permanently assembled. The current model was designed to be disassembled and reassembled to interchange between rigid and compliant tissues. The gasket gel seemed incompatible with the airway design as it would require frequent re-application, and posed a risk of invading into the airway passage due to spread. A removable, solid gasket was desired as an alternative sealing method for the current airway model.

A leak test was performed on three gasket candidates of varying thickness to determine an optimum seal for the multipart airway model. The gaskets were designed in Meshmixer and conformed to the airway model's cross-sectional shape at the mid-sagittal plane. This was then extruded to the correct thickness if 3D printed, or directly exported to a drawing exchange format (DXF) and for laser cutting. Table 7 summarises the gaskets sizes that were tested.

Table 7. Summary of the gasket candidates

Gasket candidate	Thickness	Material	Fabrication
1	0.75 mm	Tango™ Black	3D printed
2	1 mm	Latex	Laser cut
3	1.25 mm	latex + Tango™ Black	3D printed + Laser cut

It should be noted that a latex gasket of 0.5 mm was considered, however small gaps were visible between the airway halves hence it was discarded as a candidate. Gasket candidate 3 was a combination of gasket 1 and gasket 2 to achieve a thickness of 1.25 mm. The laser cut, latex gasket is shown in Figure 37.

Figure 37. Laser cut latex gasket

A leak detection method was devised to test the effectiveness of each candidate. The gasket was implemented into the airway model assembly and a continuous flow of air from an air tank was applied via the tracheal end. The setup is illustrated in the schematic in Figure 38. The air flow rate was increased until a static pressure of 400 Pa in the laryngeal region was reached. This was used as a reference pressure that the gaskets must be able to seal to, as it was the maximum recorded pressure in the closed mouth airway model for a NHFT rate of 70 L/min (Dey, 2014). It was unlikely that the current airway model would experience such a high pressure, as it was an open mouth model and was only to be tested up to NHFT levels of 60 L/min, however this ensured conservative measures for the seal test.

Figure 38. Seal and leak test setup

The leak test was repeated with a closed airway condition, where the mouth and nostrils of the airway were completely sealed using Blu-Tack™; hence any flow would be a result due to leaks in the airway and the recorded measurement would be equivalent to the leak rate of the airway. The flow rate was measured using a TSI 4040 flow meter which was connected between the tracheal end of the airway model and the tubing, which was connected to the air supply. The pressure was measured using a differential pressure sensor via a sensing probe in the pressure tap at the laryngeal region (refer to Chapter 5, Section 5.4). The flow rate was adjusted via a rotameter, however it was difficult to achieve a flowrate where the recorded static pressure reached exactly 400 Pa; therefore pressure was recorded at incrementally increasing flow rates, from 20 – 160 L/min and 0.1 – 3 L/min for open and closed tests, respectively. The results for the test are shown in Figure 39 and Figure 40.

Figure 39. Results for open airway leak test

Figure 40. Results for closed airway leak test

A percentage leak rate was calculated by finding the ratio of closed airway flow rate to open airway flow rate at 400 Pa. The flow rate at 400 Pa static pressure was extracted via interpolation of both testing conditions. The results are summarised in Table 8. It can be seen that that as the thickness of the gasket increased, a better quality seal was achieved. However, by introducing a thicker gasket, there runs the risk of small alterations in the airway geometry, as the two airway halves will be offset from each other. The gasket 1 was chosen as it gave a leak error of under 3% and this was deemed acceptable. It was also the thinnest option, mitigating the error introduced by seal thickness offset.

Table 8 Summary of leak test results

Gasket Candidate	Thickness	Flow rate at 400Pa (Open Test)	Flow rate at 400Pa (Closed Test)	Percentage Leak rate
1	0.75 mm	138 L/min	3.5 L/min	2.5%
2	1 mm	128 L/min	2.2 L/min	1.7%
3	1.25 mm	140 L/min	0.9 L/min	0.6%

Figure 41. Complete Airway Model

4.5.2 Seal Protrusion

Later in the project it was apparent that the Tango Black material used for the gasket was not robust enough for the study. Frequent disassembly of the model caused the material to tear at bolting locations. It was unfeasible to constantly reprint the material due to the cost and time associated with fabrication. A PVC material of the same thickness was used as an alternative, however this could not be laser cut to shape due to the corrosive nature of the fumes produced by the material in this process. The material was cut to shape by laser cutting a Perspex template and cutting by hand (Figure 42).

Figure 42 Perspex template and PVC gasket

The gasket would tend to deform when fastened between the two airway model halves, causing it to protrude into the airway passage. This was undesired as the protrusion could cause occlusions to the airflow. A Perspex plate was bolted to one airway half with the gasket placed between the two surfaces (Figure 43). This replicated the clamping force of an assembled model and made the internal geometry visible. Any protrusion that occurred was trimmed. This process was carried out by trial and error until desired results were achieved.

Figure 43 Perspex plate for gasket trimming

4.6 Conclusion

A physical open mouth airway model was designed, which was able to simulate internal compliant tissue conditions. This was the first airway model of its kind, as it was both an anatomically and to an extent, a physiologically correct representation of the human upper airway. The challenges that were overcome in designing such an airway are summarised in Table 9.

Table 9. Summary of challenges and solutions for developing a compliant airway model.

Challenges	Solutions
A benchtop airway model was required which could simulate rigid and compliant tissue conditions.	Fabrication of a multiple component airway with removable rigid/compliant tissue simulants.
Compliant tissue simulants could not be 3D printed as available printing materials were not soft enough to simulate the compliance of the tissues of interest.	A polymer resin that matched the elastic modulus of the compliant tissues was cast in 3D printed moulds. This achieved tissue compliance and correct anatomy of the tissues of interest.
The silicone of the compliant tissues tended to slump from self-weight.	Compliant inserts were designed to have a rigid frame as part of their structure. This gave them more structural integrity and helped with mating to the airway model.
Airway model warped from heat effects during support material removal.	The airway model was heated to glass transition and realigned.
Multiple component airway required a sealing method. Previous methods used a sealant gel, which was not suitable for the current model design.	A removable PVC gasket was designed to fit between the two airway halves. Provided a sufficient seal for up to 400 Pa of internal airway pressure.

4.7 Future Model Considerations

Throughout the project several observations were made about the airway model, which highlighted areas for potential improvement in future model design. These design considerations are from a practical point of view, which could simplify the manufacturing and improve accuracy of a multi-component airway with removable inserts.

4.7.1 Designs to Minimize Warping Effects

A flaw in the airway design is the realignment procedure that is necessary due to the warping from support material heat effects. As mentioned previously, it was not possible to completely realign due to limited clamping of the model. Small, internal separations or steps can occur between mating airway components, which alter the airway geometry and can influence the flow field. Because the current airway model consisted of two sagittal halves, which encompassed the entire passage, there was a large risk for accumulation of error. Realignment could be

removed by using a different printing technique that does not require heating for support material removal, or it could be minimized by limiting the model assembly components to the interchangeable tissue components.

As mentioned in section 4.3 one of the 3D printing considerations involved the Objet Connex, which used water blasting for support material removal, as opposed to heat for wax melting. This was undesirable due to the potential for incomplete support material removal in the complicated airway geometry, particularly in the nasal turbinate region. A study needs to be carried out that involves printing small regions of interest of the airway to investigate the quality of the support material removal.

The reason the airway shell consisted of two halves was to access the internal soft tissue inserts. Not only did this have an effect on alignment of the airway model, it also made the process of removing and inserting tissue components a cumbersome task, as the entire model had to be disassembled and reassembled for one tissue. If the model was designed in such a way where the compliant tissues of interest were the only components that could be removed from the airway, this would limit the amount of realignment required, the extent of sealing, and the down time between exchanging of compliant components.

4.7.2 Gasket Material

The leak tests in the study only considered the thickness of the gasket required for sealing the airway. This study needs to be elaborated on to find the most effective material for gasket. The properties to investigate should go as follows: Quality of sealing, material availability and cost, and geometry alterations to compensate for internal protrusion.

5 Experimental System Components

5.1 Introduction

The two main classes of measurements that were carried out in this project were static pressure measurements and capnography on the airway model during natural and NHFT assisted breathing. Physiologically accurate respiration was simulated for the airway model by coupling it to the experimental setup. This chapter describes the system components and experimental setup for simulating respiration and for conducting the relevant measurements. The procedure for these experiments will be explained in Chapters 7 and 11. Figure 44 shows a schematic of the experimental setup used.

Figure 44. Schematic of the experimental setup. Note: The pressure sensors and capnography are represented by one component in this diagram. These are actually two separate systems.

5.2 Pulsatile Lung Pump

The lung pump (Figure 45) was used to simulate respiration for the airway model, by mimicking the oscillatory motion of breathing and could be connected to the airway model via tubing. The pump comprised of a piston within an acrylic cylinder of 150mm diameter. The linear motion of the piston drove air in and out of the airway model. A gasket lined the perimeter of the piston to provide a seal with the walls of the acrylic cylinder. Piston

motion was supplied by an Astrosyn L259RE stepper motor, driven by an Astrosyn P808A stepper motor driver. The rotational motion of the stepper motor was converted into linear actuation by a Hirwin precision rolled ball screw which was connected to the piston. The stepper motor and driver were connected to a National Instruments 9401 digital module which was connected to a desktop PC and controlled via a Fourier reconstruction performed by an in-house LabVIEW program. Input for the pump motion software required a set of five Fourier coefficients, which defined the average adult natural breath waveform. The waveform could be changed by adjusting the coefficients to represent other breath patterns, such as neonatal breathing, or breathing when subjected to respiratory disorders. The work in this thesis carried out experiments with healthy adult waveforms only. Section 5.3 describes the breath pattern that was used.

The home position of the piston could be moved along the pump cylinder, to adjust its initial position when commencing testing. This was particularly necessary for the capnography measurements as the cylinder had to represent the correct functional residual capacity (FRC) of a human adult. Since the pump cylinder was an analogue lung, it was important to simulate the correct anatomical volume of lung capacity and to reproduce a physiologically accurate transport of CO_2 gas. The piston tended to drift forwards during breathing simulation and was measured to be approximately 2 mm per 300 cycles. This was negligible for static pressure measurements, however it was frequently monitored during capnography to maintain strict FRC conditions.

The pump cylinder had a bleed valve at the top, near the air outlet/inlet (Figure 45). This served as an inlet to allow CO_2 bleeding into the system, to simulate metabolic production of CO_2 gas during respiration. The CO_2 gas was supplied from a gas tank and was connected to the valve via a rubber tube. This will be explained later in section 5.5.

Figure 45. Lung pump setup

5.3 Physiological Breath Pattern

The breath waveform represented an average healthy, natural breath pattern with a tidal volume of 450 mL and a period of 4.29 s corresponding to a respiratory rate of 14 breaths per minute. The waveform was developed by Dey (2014) and has been used in previous studies (Adams et al., 2016; Dey, 2014; Van Hove et al., 2016). Dey (2014) based the breath pattern on *in vivo* measurements of the transient flow rate. These were performed for natural breathing and several NHFT levels ranging from 10 – 50 L/min on a single healthy male adult volunteer. The testing showed that the breath pattern would change depending on the level of therapy applied, however, because NHFT is typically given to patients with respiratory disorders, the *in vivo* measurements were not accurate representations of actual breath patterns. A single, natural breath pattern was used for all experimentation on both rigid and compliant airways to maintain consistency and to simplify the respiratory simulation. Although there are limitations to simulating a physiologically accurate breath pattern, the purpose of this study was to identify differences between rigid and complaint airways and therefore the breath waveform developed by Dey (2014) was deemed as an accurate enough representation for the experiments performed in this study.

The initial natural breath pattern developed by Dey (2014) had a tidal volume of 799 ml, which did not conform to the average tidal volume of 500 ml for an adult, however the measured respiratory rate of 12 breaths per minute was similar to the average, of 11.8 breaths per minute (Tortora & Derrickson, 2011). Dey (2014) suggested that the procedure for the *in vivo* measurements increased the anatomical dead space due to the facemask used in the experiment. The breath pattern was hence scaled to conform to studies by Tobin et al (1983), who performed breath experiments on 65 subjects without increasing the anatomical dead space. The developed natural breath pattern of 14 breaths per minute and tidal volume of 450 ml was a more accurate representation as it was similar to the average measured breaths of 383 ml tidal volume and 16.6 breaths per minute respiratory rate (Tobin et al., 1983). A single cycle of the breath pattern is shown in Figure 46, which shows the flow rate of air exiting the pump measured by the flow meter.

Figure 46. Breath pattern supplied by the pump, measured with a TSI 4040 flowmeter

5.4 Pressure testing elements

One of the experiments conducted on the airway model was measuring the transient static pressure at various points along the airway. Two pressure sensing systems were used, each comprised of different transducer models, as during the project, the original pressure sensing system, built and used for previous airway studies, was upgraded with new sensing elements that were more suited to the project. The first set of pressure transducers were S&C Honeywell differential transducers, which had a range of -2.5 kPa to 2.5 kPa with a resolution of 0.1 Pa and were arranged in a system of 32 elements. This pressure sensing system was used for seal testing the airway model, described in chapter 3, however, this was replaced by a second pressure sensing system, which was available to use by the time static pressure testing commenced. The second system consisted of a 10 element pressure sensing system with AMS 5915-0005-D-B bidirectional differential pressure sensors with I²C interface (Figure 47). These had a measurement range of ± 500 Pa with a resolution of ± 1.5 %. As described in Chapter 4 Section 4.2.3, the airway had specially designed taps to accommodate for pressure sensing elements. The I²C sensors do signal conditioning on the same chip as the pressure sensor and output a digital signal, hence less opportunity for noise to be picked up. Also, the smaller range is better matched for the experience, as less gain is required hence lower noise. The pressure sensors used for this project were adapted to 1 mm diameter stainless steel sensor probes that could be inserted into the airway pressure taps to conduct measurements at the specific airway regions. The sensor probes were connected to the pressure transducers via a rubber tubes. Once the probes inserted into the tap, Blu-TackTM was placed around the tap to seal any small leak (Figure 48). The pressure sensing system was connected to a desktop PC via USB and Matlab[®] (Mathworks, Natick, MA, USA) was used to display a real-time stream of the pressure measurements and to record results at a sampling frequency of 25 Hz.

Figure 47. The second pressure sensing system used for the static pressure experiments. Single pressure sensor (left) and ten pressure sensor setup (right)

Figure 48. Example of a sealed tab with pressure sensing probe.

5.5 Capnography and CO₂

The second measurement tested for CO₂ concentration for natural and NHFT breathing. This was simulated by bleeding a set flow rate of CO₂ gas to reproduce metabolic CO₂ flow into the human respiratory system. This corresponded to a maximum CO₂ partial pressure of 40 mm Hg measured at the tracheal end, and represented the

physiological alveolar CO₂ concentration (Tortora & Derrickson, 2011) (refer to Chapter 11, Section 11.2 for experimental procedure). The CO₂ gas was supplied by a gas tank which was connected to the bleed valve located on the top of the pump cylinder. A King Instruments 7430 series low flow rotameter was connected to the tubing between the CO₂ tank and the pump cylinder. This was used for regulating the flow of CO₂ gas into the lung pump. The CO₂ concentration was measured using an Oridien Microstream™ microMediCO₂™ OEM Module (Figure 49). This had a measuring range of 0 – 150 mmHg, with a sampling rate of 20 Hz and an accuracy of ± 2.4 mm Hg for the concentrations which were measured in this project (up to 41 mmHg). The capnography was connected to a Surestream CO₂ sample line, which had a sensing probe attached to the end, similar to the static pressure sensing probes. The probe could also be inserted into the airway models' pressure taps, and measure CO₂ concentration at designated points. The capnograph probe also required a Blu-tack™ seal around the tap. The capnography setup was connected to a desktop PC and CO₂ concentration measurements were recorded using software provided by the capnography manufacturer (Monitor miniMediCO₂).

Figure 49. Oridien Microstream™ microMediCO₂™ capnography used for the CO₂ experiments

5.6 Optiflow Nasal Cannula and Airvo

5.6.1 Airvo

The NHFT was supplied by Fisher & Paykel Healthcare's Optiflow™ 8 series nasal cannula and Airvo™ 2 humidifier. The humidifier is responsible for providing the air flow for the nasal high flow. It consists of a flow generator, which intakes air and passes it through a chamber filled with water, which is constantly heated via a heater base. This setup conditions the air to 37°C and 100 % relative humidity (RH). The flow generator has adjustable settings where NHFT flow rate can be varied from 10 L/min up to 60 L/min. In this project, NHFT flows of 30 L/min and 60 L/min were used. The Optiflow™ nasal cannula is connected to the Airvo2 humidifier via a corrugated outlet tube. The tube contains a heater wire throughout the length, to maintain the air consistently at 37 °C and to prevent condensation from occurring within the tube. The static pressure and capnography measurements were conducted with 30 L/min and 60 L/min NHFT flow rates. Dry cannula air, heated to 37°C was used for this project as humidified air caused condensation to occur inside the airway model. The water droplets formed in the airway compromised the anatomy of the internal and also tended to block the pressure taps which prevented measurements. It was found that pressure measurements would decrease by approximately 5 % when using dry cannula air, compared to 100 % RH, due to the difference in fluid properties. However, because the purpose of the study was to investigate the difference between rigid and compliant conditions, this was deemed negligible, as long as dry air was used consistently for each experiment.

The NHFT flow rates supplied with the Airvo™ 2 humidifier were measured by removing the connected cannula and coupling the tube from the system to the TSI flow meter. It was discovered that the actual flow rate provided by the therapy was lower than the flow rates specified on the humidifier. The flow rates are summarised in Table 10. For the sake of convention, NHFT flow rates will be referred to by the specified flow rate throughout the thesis.

Table 10. Measured NHFT flow rates

Specified Flow Rate	Measured Flow Rate
NHFT 30 L/min	24.5 L/min
NHFT 60 L/min	49.8 L/min

5.6.2 Cannula Size

Fisher & Paykel Healthcare has 3 size ranges for the adult Optiflow™ nasal cannula: small, medium and large. In a clinical environment, size selection is qualitatively assessed by the size of a patients' facial geometry and comfort. The prongs of the nasal cannula should be able to enter the nostrils and no occlusion should occur. The

cannula size for the experiments was also assessed in a qualitative manner, by fitting the different sizes onto the airway model and visually observing the interface between the model and the cannula. It was determined that the medium sized cannula was the most suitable for the airway model. The prongs of the small cannula did not penetrate the nostrils at a sufficient depth (Figure 50 (left)) and there was risk of the NHFT jet not completely flowing into the nasal cavity, hence the small cannula size was discarded. The large cannula size would tend to deform when placed on the model. Its large prong diameter and the depth of penetration in the cavity caused it to distort when pushed against rigid septum and nostril walls, leading to small occlusions in the cannula (Figure 51). The medium sized cannula was deemed as the suitable choice as it entered the nasal cavity as the prongs entered the nasal cavity at a reasonable depth without experiencing any deformation (Figure 50).

Figure 50. Small cannula (left) and medium cannula (right) adapted to the airway model.

Figure 51. Left shows a large cannula adapted to airway model .Cannula outlet region cannot be seen due to the depth of insertion. Right shows an axial cross-section of the nasal cavity illustrated in green with large nasal cannula and regions where prong deformation occurs.

5.6.3 Cannula Positions

The nasal cannula was fitted to the facial geometry via an adjustable strap that is designed to fit over a patients' head, and sit on top of the ears. Upon initial experimentation in this study it was observed that nasal cannula was easy to misposition which had the potential to vary the flow field, as the jet of air would enter the nasal cavity at a different angle. A sensitivity study was carried out to investigate the influence of different cannula positions. Three positions were tested: A middle position, where the midpoint between the prongs of the nasal cannula was lined up with the centre of the airway, defined by a join between the two airway model halves; left-most position, where the cannula was moved as far left without (approximately 2 mm) bending the prongs; and a right-most position (approximately 4 mm) (Figure 52). Static pressure was measured at the nasopharynx (pressure tap 13) at a nasal high flow rate of 60 L/min. Figure 53 shows the static pressure measurements for one phase averaged breath cycle, for each cannula position. Each position was tested with three repetitions with largest uncertainty of ± 4.8 Pa. The results show that the cannula position can alter the measurements conducted in the airway with average pressure differences of 7.2%, 14.3% and 20.5% between middle vs left, middle vs right positions, and left vs right cannula positions, respectively. It was therefore concluded that cannula position was a factor that had to be controlled in the experiments. To maintain a constant position, the cannula was fastened to the airway's facial geometry with two bolts on either side. The middle position was chosen as this is how the nasal cannula is normally worn.

Figure 52. Nasal cannula positions left-most, middle and right-most positions (from left to right).

Figure 53. Airway pressures for one averaged breath cycle with different cannula positions.

5.7 Miscellaneous Components

During testing, the model was mounted to a wooden bracket, which was on a 30 degree incline. A static pressure measurements were simultaneously performed on up to ten tap locations along the airway. The mounting bracket allowed ease of access to the pressure taps during testing and prevented awkward positioning when multiple pressure probes were inserted to the model. The model was placed in a supine position, and fixed to the mount by a cable tie around the pharynx. Figure 54 shows the airway model testing position on the wooden bracket.

Figure 54. Airway model testing position.

A TSI 4040 thermal mass flowmeter (Figure 55) with accuracy of $\pm 2\%$ was attached between the airway tracheal end of the airway and the pulsatile pump. This was connected between the airway model and the lung pump.

Figure 55. TSI 4040 flowmeter

From the flowmeter to the airway, a pipe of 20 mm in diameter and 120mm in length, which conforms to the dimensions of a trachea in a male adult (Gray, 2009). With the absence of the trachea in the model, it was desired to replicate the physiological development of airflow through the respiratory system with a passage similar to the trachea. Although a smooth pipe geometry was a very simplified method to model a trachea, computational studies have shown good agreement of airflow development between an anatomically correct trachea and idealized smooth pipe geometry (Brouns et al., 2006). An intermediary, flexible corrugated tube was used to connect between the lung pump and the flowmeter. As mentioned in section 5.2, it was important to reproduce the internal airway volume in an adult, to replicate a physiologically accurate transport of gas. The combined volume of the pump cylinder (just after an exhale), the intermediary tube and the flow meter was approximately 2400 mL, and was representative of the FRC. The combined volume of the trachea tube and the airway model was approximately 150 mL and representative of the anatomical dead space (Tortora & Derrickson, 2011).

As well as the TSI flow meter, a Honeywell AWM720P1 flowmeter was also used for the project (Figure 56). This was required for a supplementary measurement to determine how the air flow was partitioned between the nasal and oral passages during respiration (refer to chapter 6). This is a uni-directional flowmeter and had a measurement range of up to + 200 L/min and an accuracy of $\pm 0.3\%$ of the reading.

Figure 56. Honeywell Flowmeter

An endoscopic VGA camera was also used in additional experiments, to visualise the internal compliant components during simulated breathing. This was 0.3 MP camera with a resolution of 640 x 800 with a USB interface, and was required to be plugged into a desktop for a livestream recording. The cable and camera head diameters were 4 mm and 7 mm, respectively. Because of the size of the camera, it had to be inserted via the trachea end of the airway model, as it would not fit through the nasal or oral passage of the airway. The camera is shown in Figure 57.

Figure 57. Endoscopic Camera

6 Flow Rate Distribution in an Open Mouth Airway

6.1 Introduction

During respiration of the open mouth model, air enters and exits the airway via two passages: the oral passage and the nasal passage. Oral passage refers to the region from the entrance of the mouth to the anterior oropharynx. The nasal passage encompasses the nasal cavity, nasopharynx and velopharynx. The flow passages meet or split (depending on the direction of the flow) at the oropharynx. This section explains how the air is partitioned between the nasal and oral passages during peak inspiration and peak expiration for the different levels of NHFT used. Flow rates were measured for a rigid and compliant soft palate airway condition, and the results are shown in this chapter, but will be discussed in later chapters (Chapter 8). The purpose of this chapter is to understand the general flow pattern in the open mouth airway, which will be helpful in understanding the pressure and capnography results.

6.2 Experimental Procedure

Flow rate distribution between the nasal cavity and oral cavity was quantified for natural breathing and NHFT assisted breathing on the *in vitro* model. During natural breathing, the flow rate was measured at the mouth and at nose with the Honeywell AWM720P1 flowmeter (refer to Chapter 5, Section 5.7). The mouth and nose flow rate measurements had to be recorded with two different experiments as only one flowmeter was available. The mouth flow rate could be recorded by directly attaching and sealing the flow meter to the mouth opening with Blu-Tack™ (see Figure 58 (left)). The nose measurements required a custom made mask which contoured the surface of the model's face and encompassed the nose (see Figure 58 (right)). The mask had an outlet at the end to allow for attachment of the flowmeter and was sealed to the face with blu-tack. For both mouth and nose measurements the quality of the seal was checked qualitatively by physically feeling for drafts, and by applying a detergent-water solution at the seal interface. A leak would be identified by the formation of bubbles on the seal. Because the flow meter was uni-directional, separate experiments had to be conducted for inspiration and expiration. Because of this limitation, only peak flow rates were assessed. For NHFT assisted breathing, the flow rate measurements were made for the mouth only, as the face mask could not fit to the airway with the cannula on the model. Attempts were made, however it was difficult to place the cannula in its fixed position specified in Chapter 5, Section, 5.6.3. Once the airway model had the flow meter attached, it was coupled to the pulsatile pump, and the pump was activated. Measurements were recorded for 20 breath cycles, and each experiment was repeated 10 times.

Figure 58. Flow measurement setup for the airway model. The setup for the mouth (left), used for both natural and NHFT breathing condition, and the setup for the nose, with the nasal mask (right) for the natural breathing condition only. The figures depict the setup for a natural breathing condition.

6.3 Data Processing

The data was processed to obtain the mean peak expiratory and peak inspiratory flow rates for a single breath. A total of 200 breath cycles were recorded for inspiration and expiration, for each breathing case. The peak flow rates were extracted from each breath cycle, and these were averaged to determine the mean peak expiratory and inspiratory flow rates. An uncertainty was also determined by calculating 2 standard deviations of the mean peak flow rates. This was performed with Matlab®.

6.4 Flow Rate Pattern and Measurements

For natural breathing the nasal and oral distribution of air can be defined by the following equation:

$$Q_{Respiration} = Q_{Oral} + Q_{Nasal}$$

Where $Q_{Respiration}$ denotes the volumetric flow rate applied by the pump that simulates lung flow rate (refer to Chapter 5, Section 5.2). At peak inspiration and peak expiration, the flow rates are 19.7 L/min and 13.8 L/min, respectively, and these are held constant at their respective peak breathing phases, regardless of whether natural or NHFT breathing is simulated, as the breath pattern is fixed by the pump. The nasal flow rate, Q_{Nasal} , refers to the volumetric flowrate that travels through the nasal cavity, nasopharynx and velopharynx; and the oral flow rate, Q_{Oral} , refers to the volumetric flow rate that enters the mouth and travels through the oral cavity, during respiration. On inspiration these two streams meet in the oropharynx regions and proceed down the pharynx toward the tracheal end. On expiration, the expired stream of air travelling from the trachea partitions at the oropharynx,

into the oral and nasal flows and these flows travel outward in their respective passages. This pattern is illustrated in Figure 59.

Figure 59. Diagram of the sagittal cross-section of the upper airway. Illustration of air flow streamlines for natural breathing during inspiratory (left) and expiratory (right) phases.

Flow measurements showed that the flow is approximately evenly partitioned between the nose and mouth during natural respiration. On inspiration nose and mouth flow rates are 9.9 ± 0.4 L/min and 9.7 ± 0.3 L/min, respectively, which corresponds to 50.3 ± 2.0 % and 49.2 ± 1.5 %. On expiration nasal and oral passages 7.2 ± 0.4 L/min and 6.6 ± 0.3 L/min, which is 52.2 ± 2.9 % and 47.8 ± 2.2 % of the total expired flow.

During NHFT assisted breathing, the flow provided by the cannula, Q_{NHFT} , separates into two pathways.

1. A portion of the Q_{NHFT} proceeds through the nasal cavity and travels into the pharynx and onward to the lungs. With NHFT assisted breathing, this volume of air will be referred to as Q_{Nasal} .
2. A portion of the Q_{NHFT} will turn and leave the airway via the small clearance between nostril and the cannula prong. This clearance will be referred to as the leakage area and hence the outward flow will be referred to as the nasal leak rate (Q_{Leak}).

Although nasal flow rates could not be measured during NHFT assisted breathing, a tuft flow visualization indicated that outward flows occurred via the nose throughout the entire respiration cycle for 30 L/min and 60 L/min therapy levels. This confirms that flow from nasal leak rate must exist. An outward nasal flow would be expected during expiration, however this can also occur during inspiration when the flow rate of the therapy

exceeds inspiratory demand, as excess flow must turn and leave the nasal cavity. Therefore nasal flow rate is the difference between therapy flow rate and the outward the outward nasal leak.

$$Q_{Nasal} = Q_{NHF} - Q_{Leak}$$

Inspiration with NHFT at 30 L/min (Figure 60 left) can be defined with the following equation:

$$Q_{Inspiration} = Q_{oral} + Q_{Nasal} = Q_{oral} + Q_{NHF} - Q_{Leak}$$

During expiration with NHFT 30 L/min (Figure 60 right), although there is a greater nasal leak rate then on inspiration, a portion of cannula air persists through the nasal passage and leaves the airway via the oral cavity, which was also shown by Spence (2011). Hence $Q_{Expiration}$ for this case is defined by the following equation:

$$Q_{Expiration} = Q_{oral} - Q_{Nasal} = Q_{oral} - Q_{NHF} + Q_{Leak}$$

Figure 60. Diagram of the sagittal cross-section of the upper airway. Illustration of air flow streamlines for NHFT 30 L/min breathing during inspiratory (left) and expiratory (right) phases.

During NHFT at 30 L/min at peak inspiration, 14.5 ± 0.5 L/min of air enters through the nose, and 5.2 ± 0.5 L/min enters through the mouth, which corresponds to 73.6 ± 2.5 % and 26.4 ± 2.5 % of the inspiratory demand, respectively. There is an outward flow of 10.1 ± 0.5 L/min due to the nasal leak rate, and this is 41.2 ± 2.0 % of the therapy flow (remembering that the actual flow of the therapy is 24.5 L/min (refer to Chapter 5, Section 5.6.1). On expiration 17.4 ± 0.7 L/min flows outward through the mouth and 21.1 ± 0.8 L/min via the leak area, which corresponds to 45.4 ± 1.8 % and 55.1 ± 2.1 % of the total air leaving the airway, respectively. The portion of

cannula flow that persists via the nasal passage on expiration is 3.4 ± 0.7 L/min and is 13.8 ± 2.8 % of the total therapy flow.

During NHFT 60 L/min at peak inspiration, there is a portion of air that exits via the oral passage (Figure 61 left) as the air entering the nasal passage, Q_{Nasal} , exceeds the inspiratory demand, even with nasal leak rate. Hence to hold the conservation of mass flow, there must be a portion of air that leaves via the mouth. The following equation defines inspiration with NHFT of 60 L/min:

$$Q_{Inspiration} = Q_{Nasal} - Q_{oral} = Q_{NHF} - Q_{Leak} - Q_{oral}$$

During expiration with NHFT 60 L/min, all air is expired via the mouth, while there is a portion of cannula flow entering the nasal cavity, similar to expiration with NHFT 30 L/min (Figure 61 right). Expiration with NHFT 60 L/min can be defined with same equation for NHFT 30 L/min inspiration.

Figure 61. Diagram of the sagittal cross-section of the upper airway. Illustration of air flow streamlines for NHFT 60 L/min breathing during inspiratory (left) and expiratory (right) phases.

During peak inspiration with NHFT at 60 L/min, the flow passing through the nasal passage is 30.0 ± 0.3 L/min and is equivalent to 152 ± 1 % of the inspiratory demand. The excess flow that leaves the mouth is 10.3 ± 0.2 L/min and the leak rate is 19.8 ± 0.3 L/min, and these correspond to 20.7 ± 0.4 % and 39.8 ± 0.6 % of the therapy flow, respectively. On expiration 29.2 ± 0.8 L/min leaves through the mouth, and 34.5 ± 0.9 leaves via the leak area, which corresponds to 45.9 ± 1.3 % and 54.2 ± 1.4 % of the total flow leaving the airway, respectively. The portion of cannula flow that persists in the nasal cavity is 15.3 ± 0.9 L/min and is 30.7 ± 2.9 % of the therapy flow.

The nasal, oral and leak flow rates are summarised in the Table 11 . These are shown for the rigid airway and for the airway with a compliant soft palate condition. The results are only summarised in this chapter, and will be discussed in Chapter 8, as they are supplementary for the compliant soft palate pressure measurements.

Table 11. Flow rates during peak inspiration and peak expiration for all breathing cases. These area summarised for the airway with a rigid and compliant soft palate condition (denoted by Comp SP).

7 Static Pressure Experimental Procedure and Data Processing

7.1 Experimental Procedure

Static pressure tests were carried out with pulsatile lung pump and the pressure testing elements described in Chapter 5. The airway model was fixed on the inclined wooden bracket in supine position and coupled to the pulsatile pump via the tubing. The pressure probes were connected to the airway pressure taps, and Blu-Tack™ was applied between the interface of the probe and the tap to prevent potential leaks. Given the number of pressure sensing elements that were available, up to ten taps could be measured simultaneously. The pulsatile pump was initialized and the pressure measurements were recorded after the pump completed 5 initial cycles. This was to allow the breathing pattern in the airway to reach a steady cycle. The pressures were recorded for approximately 30 breath cycles for each pressure tap. Each test was repeated 10 times. The static pressure tests were also carried out for the NHFT assisted breathing at 30 L/min and 60 L/min with the exact same procedure only with a nasal cannula fitted to the airway. Before a test was repeated, all pressure probes were removed and replaced back into the taps and nasal cannula was refitted for the NHFT assisted tests. Four configurations were tested for: The rigid airway model and each compliant tissue condition. This was to isolate each specific compliant component and to investigate how each individual tissue affected breathing.

Two supplementary tests were also carried out with the pressure experiments. The first test involved the rigid airway with the mouth completely sealed with Blu-Tack™ to approximate a closed mouth condition. The second test was for the compliant soft palate airway condition, with a ‘face-down’, prone orientation, to investigate potential gravitational effects. The exact same pressure testing procedures that are explained in the previous paragraph were implemented for these two tests.

Figure 62 shows the locations of the taps on the airway model. Each airway region had 3 – 5 pressure taps designated to it. Due to the large amount of taps pressure results in each region of the pharynx will be represented by the posterior pressure tap. Although there was a small amount of variation between pressure taps within the same the region, this variation was of little use for the compliant vs rigid tests. The extra taps were used as validation to confirm whether a tap was producing correct results when an outlier measurement was suspected. The pressure taps at the nostrils and mouth opening (pressure taps 1 – 4) had a low signal-to-noise ratio and made it difficult to extract useful information and were omitted from testing. This may have been due to turbulence from the cannula, flow separation in the oral cavity or recirculation in the oral cavity. The taps on the left and right side of the oral cavity (taps 5 and 6) were used during natural breathing, however were omitted for NHFT tests they did not produce any distinguishable results due to large amount of noise. The taps at the superior nasal concha of

the nasal cavity (7 and 8) were also omitted as the results would vary drastically between repetitions. It is deduced that the flow field in this region is very sensitive to cannula position, despite efforts to fix it to the airway model.

Figure 62. Tap locations along the airway. The numbers represent the taps, and the coloured lines correspond to their position on the airway. Red = left sagittal, orange = right sagittal and green = posterior or superior. The coloured airway sections correspond to the different regions in the upper airway.

7.2 Data processing

The pressure measurements were processed to obtain a mean pressure profile for a single breath cycle at each tap location. The first step required the implementation of a digital filter to increase the signal-to-noise ratio of the raw data. A Savitzky-Golay (SG) filter was used which applies a least square method for signal smoothing. Figure 63 shows an example of the raw data obtained from the pressure measurements, and the resultant signal after applying the SG filter.

Figure 63. Savitzky-Golay filter implementation on a raw pressure signal.

After the results were filtered, 20 sequential breaths were extracted from the data set by truncating the first the 5 cycles and the remainder cycles at the end of the set. The first 5 cycles were truncated as a precaution in case the measurements commenced before steady cycle was reached. The 20 cycles from each test were separated into individual breaths and then all of the 200 cycles were phase averaged to obtain a mean pressure profile for a single breath, at each tap location. An uncertainty for each point of the pressure profile was obtained from 2 standard deviations from the 200 cycles used for the phase average. Figure 64 shows an example of a mean pressure profile, with error bars corresponding to the uncertainty. The peak pressures during inspiration and expiration were the values of interest in this study, and they were extracted assess rigid and compliant results.

Figure 64. An example of a mean pressure profile for a single breath at an arbitrary airway location.

8 Pressure Test: Compliant Soft Palate

8.1 Introduction

The following chapter discusses the pressure test results from the compliant soft palate airway condition during natural breathing and NHFT assisted breathing at 30 L/min and 60 L/min. The pressure testing method is described in Chapter 7. The pressure results are compared to the results obtained from the rigid airway condition to determine how soft palate compliance affects breathing. This chapter is sectioned into three parts, which correspond to each breathing condition (natural breathing, NHFT 30 L/min and 60 L/min). Each breathing condition is sub-sectioned to the inspiration and expiration phases, and the peak airway pressures for these phases are analysed and discussed.

A pressure tap schematic of the airway is displayed in Figure 65, and Table 12 summarises the taps and regions which were investigated. The pressure results are shown for the posterior taps in the pharynx, as these taps are representative for the region.

Table 12. Airway tap locations and the corresponding abbreviations used in the graphs

Region	Location	Abbreviation	Tap Number
Oral Cavity	Oral Cavity Left	OC L	5
	Oral Cavity Right	OC R	6

	Laryngopharynx	LP	23
	Larynx	L	24
	Trachea	Tr	28

Figure 65. Airway Tap Location Map

8.2 Natural Breathing: Inspiration

Figure 66 summarises the airway pressures measured at peak inspiration along the airway for an open mouth rigid and compliant soft palate air condition, and a closed mouth rigid airway. It is clear that the compliant soft palate affects the pressures globally along the airway. The difference between rigid and compliant airway pressures are summarised in Figure 67. The following observations can be made when comparing the peak inspiratory pressures between open mouth rigid and compliant airways:

1. In the Oral Cavity (taps 5 and 6) the compliant pressures more negative than their corresponding rigid pressures. The difference between rigid and compliant soft palate conditions are 0.9 ± 0.4 Pa and 0.7 ± 0.6 Pa.

2. In the upper pharynx (taps 13, 14, and 17), airway pressures for the compliant soft palate condition are lower than their corresponding rigid pressures, with the smallest difference 0.9 ± 0.6 Pa.
3. In the lower pharynx (taps 18, 23, 24 and 28) the pressures in the compliant airway are significantly more negative than their corresponding rigid pressures. In this region, the differences between rigid and compliant peak inspiratory pressures range from 3.2 ± 1.2 Pa to 4.5 ± 2.1 Pa.

Figure 66. Peak inspiratory static pressures measured along the airway during natural breathing for both an open mouth rigid and compliant soft palate airway condition, and a closed mouth rigid airway. Error bars correspond to an uncertainty of 2 standard deviations.

Figure 67. Difference in peak inspiratory pressures between open mouth rigid and compliant soft palate airway conditions (compliant minus rigid). The results are for natural breathing. Error bars correspond to an uncertainty of 2 standard deviations.

The difference between rigid and compliant soft palate airway conditions must arise from some flow induced motion or deformation of the compliant soft palate. This will consequently affect the flow pattern in the airway. During the experiment, an endoscopic camera was inserted into the compliant airway. During natural breathing there was no observable movement of the compliant soft palate which may be due to the limited field of view and the poor resolution of the camera. However, two hypotheses are considered for how the compliant soft palate may be affected by the flow, and how this may result in alteration to the flow pattern. The first hypothesis, the air flow causes the soft palate to move toward the anterior of the airway causing a widening in the velopharyngeal passage. The second, alternative hypothesis is contrary to the first, where the soft palate tends toward the posterior on inspiration, causing a reduction in cross-sectional area at velopharynx. The possible explanations for how the air flow may cause the hypothesised movement of the soft palate are listed below:

- Shear stresses acting on both anterior and posterior sides of the soft palate body from the oral and nasal flows.
- The difference in pressures at the anterior and the posterior of the soft palate body drive the motion.
- The significant negative pressures in the lower pharynx (oropharynx to trachea), which are downstream of the soft palate. This may induce a pulling like force parallel to the direction of the flow, that could reposition the compliant soft palate.
- Gravitational effects causing the soft palate to slump under its own weight.

The reader should be reminded that during open mouth inspiration, the air enters the airway through two openings- the oral and the nasal passages (Chapter 6). The two inspired streams meet at the oropharynx and proceed to make their way into the lungs to meet the inspiratory demand. The nasal flow rate must pass through the nasal cavity, the nasopharynx and the velopharynx, until it reaches the oropharynx where it meets the oral flow. Figure 68 shows a schematic of the air flow in the open mouth airway.

Figure 68. Airflow schematic peak inspiration.

Hypothesis I - The soft palate moves toward the anterior on inspiration, increasing the velopharyngeal cross-sectional area. This will reduce the resistance in the regions upstream to the velopharynx, such as the nasopharynx and nasal cavity (nasal passage). Consequently, the passage that connects the oral cavity to the oropharynx, which will be referred to as the oral-to-pharynx passage, must narrow, as part of this passage is on the anterior side of the soft palate body and will be affected by the motion. The reduction in cross-sectional area of the oral-to-pharynx passage must therefore increase the resistance of this passage. Compared to the rigid airway, the compliant airway now has a lower resistance in the nasal passage, and vice versa for the oral passage. This shift in resistance in the compliant airway will alter the partitioning of inspired airflow between nasal and oral passages, as air flow will prefer the path of least resistance. The flow rates in the oral and nasal passages were measured for the rigid and compliant soft palate airway conditions are summarised in Figure 69 (refer to Chapter 6). The compliant airway has more flow rate inspired via the nasal passage, than the rigid airway by 1.3 ± 0.9 L/min, and therefore less flow rate via the oral passage by approximately the same amount.

Figure 69. Air flow distribution during peak inspiration in natural breathing, with the absolute difference between the two. The error bars correspond to an uncertainty of 2 standard deviations.

Due to the hypothesised reduction of resistance in the velopharynx of the compliant airway, inspired air will prefer to enter via the nasal passage, and hence why the compliant airway has more flow in this passage than the rigid airway. On inspiration, airflow from atmosphere is driven into the airway due to the negative pressure produced by the pulsatile pump. A greater flow rate during inspiration will correspond to more negative static pressures. This can explain why the peak pressures in the upper pharynx of the compliant airway are more negative than the corresponding pressures in the rigid airway by 0.9 ± 0.6 Pa to 0.5 ± 0.2 Pa (Figure 67). Less air flow enters via

oral passage of the compliant airway as this region will have a greater resistance than that of the rigid airway. Hence why the compliant airway has less negative pressure in the oral cavity than the rigid airway.

Hypothesis II - The soft palate tends toward the posterior on inspiration causing a reduction in cross-sectional area at velopharynx. In this case a narrowing of the velopharynx will consequently cause a widening of the oral-to-pharynx passage. An opposite outcome would occur to what was stated in hypothesis I. The compliant airway would have a resistance shift such that the nasal passage would have a greater resistance, while its oral passage would have a lower resistance, compared to the rigid airway. The inspired air would prefer to enter via the oral cavity of the compliant airway, and hence the measured pressures in this region would be more negative; while less flow entering via the nasal cavity would cause pressures to be less negative at all points from the nares to the point where the soft palate increases the resistance and hence the local pressure drop. This is inconsistent with what is seen in the results as the pressures in the upper pharynx (taps 14 to 17) of the compliant airway are more negative than the corresponding rigid and less negative in the oral cavity (Figure 66). This is also inconsistent with the measured nasal and oral flow rates in Figure 69. For this hypothesis to be correct it would be expected that the compliant airway would have more air entering the oral cavity, compared to rigid, and vice versa for the nasal passage. However, this hypothesis can explain the pressure difference between the rigid and compliant velopharynx, which can be attributed to the Bernoulli Effect. The reduced cross-sectional area in the velopharynx of the compliant airway will cause an acceleration of the flow and a decrease in pressure.

There is more evidence that supports hypothesis I, as the expected consequences agree with the airway pressure measurements and the flow rate distribution between oral and nasal cavities. Hypothesis II can only explain the differing velopharyngeal pressures between compliant and rigid airways, but fails to explain the variation in pressure measurements in the nasopharynx and the oral cavity. Hypothesis II is also inconsistent with results from the flow measurements.

Lower Pharynx

The lower pharynx defines the locations between the oropharynx and the tracheal end (taps 18, 23, 24 and 28). This region has the most significant difference in peak inspiratory pressures between the rigid and compliant airway conditions. The absolute differences range from 3.2 ± 1.2 Pa to 4.5 ± 2.0 Pa. It should be remembered that the oral and nasal flows meet in the oropharynx, and hence the flow rate in the lower pharynx will be equivalent to inspiratory demand; also, the flow rate will be the same for both rigid and compliant airways as it is fixed by the pulsatile pump. Regardless of how the soft palate moves, both hypothesised cases describe a constriction to the flow in either the oral or nasal passages and an expansion in the other. This constriction may cause flow

separation as the air enters into the lower pharynx, leading to a pressure loss. This can explain why the lower pharynx is affected by compliance.

Figure 66 also compares the peak inspiratory pressures for a rigid, closed mouth airway condition and they are significantly more negative, than the pressures in both open mouth rigid and compliant airways. This indicates that nasal breathing has much greater resistance than oral-nasal breathing. This would be expected, as the entire volume of air demanded for inspiration must enter the airway through a single passage, as opposed to the parallel passages of an open mouth airway. It is also expected that in the case of a closed nose condition, where air was inspired exclusively through the mouth, a similar outcome would occur, as this too would cause a greater resistance in the airway when comparing to oral-nasal breathing. Resistance was calculated for all three airway conditions using the equation below, where ΔP is the pressure difference between airway openings (atmospheric) and at the tracheal end. The flow rate, Q , corresponded to peak inspiratory flow rate which was 19.7 L/min. Table 13 summarises the resistance of the different airway conditions.

$$R = \frac{\Delta P}{Q}$$

Table 13. Summary of resistance in different airway conditions during natural inspiration

Airway Condition	Resistance (Pa min L⁻¹)
Rigid Open Mouth	1.37 ± 0.04
Compliant Open Mouth	1.53 ± 0.04
Rigid Closed Mouth	2.98 ± 0.06

Although both hypotheses stated that there is a reduction in resistance in either the oral or nasal passage, it can be seen that the total resistance of the open mouth compliant airway is greater than that of the open mouth rigid (Table 13). Therefore the ultimate effect of soft palate compliance increases the airway resistance. Under the premise of hypothesis I, when the oral-to-pharynx passage narrows, it can be said that the open mouth model approaches a closed mouth condition. This is evident as the open mouth compliant airway pressures tend away from the rigid open mouth pressures, and approach the values measured for the rigid closed mouth airway. A similar statement can be said for hypothesis II, where there is a narrowing of velopharynx, and a restriction to the nasal passage; hence, the open mouth model approaches a closed nose condition. For the airway to have a minimum resistance, the flow would have to be distributed equally between the oral and nasal passages, indicating that the nasal and oral routes have equal resistances. As resistance is non-linear with area, opening up one passage wider does not compensate for narrowing the other by the same amount. This can help explain why the compliant airway has a net increase in resistance, compared to the rigid airway. It can also explain why the pharynx of the compliant

airway is affected by compliance, including the regions distal to soft palate, such as the oropharynx to trachea regions.

To conclude this section, the findings and hypothesised mechanisms are summarised in Table 14.

Table 14. Summary of results

Breath	Phase	Results (compliant relative to rigid)	Hypothesis
Natural Breath	Inspiration	<p><u>Pressures</u>: More negative in the pharynx; less negative in the oral cavity.</p> <p><u>Flow rate</u>: More flow in the nasal passage; less flow in the oral cavity</p>	<p>Anterior soft palate movement → nasal passage resistance decreases, oral passage resistance increases. → flow preference shift → Greater flow on inspiration = more negative pressures; vice versa for lower flow</p>

8.3 Natural Breathing: Expiration

Figure 70 summarises the peak expiratory pressures for open mouth rigid and compliant soft palate airway conditions, and for a closed mouth rigid airway condition during natural breathing. The difference in peak pressures between open mouth rigid and compliant airways are summarised in Figure 71. At peak expiration, an opposite outcome occurs as seen in peak inspiration, as the pharyngeal pressures in the compliant airway are more positive than those in the rigid airway and vice versa for the oral cavity. The results are summarised as follows:

1. In the oral cavity the compliant pressures are lower than the corresponding rigid pressures by 0.6 ± 0.3 Pa and 0.3 ± 0.1 Pa.
2. In the upper pharynx (tap 13, 14 17 and 18) the pressures in the compliant airway are more positive than corresponding rigid pressures by 0.3 ± 0.2 Pa to 0.5 ± 0.4 Pa.
3. In the lower pharynx (taps 18, 23, 24 and 28) the pressures of the compliant soft palate airway area greater than the pressures in the rigid airway by 1.9 ± 0.9 to 2.4 ± 0.6 . The compliant vs rigid difference for this region is the most significant during peak expiration.

Figure 70. Peak expiratory static pressures measured along the airway during natural breathing for both an open mouth rigid and compliant soft palate airway condition, and a closed mouth rigid airway. Error bars correspond to an uncertainty of 2 standard deviations.

Figure 71. Difference in peak inspiratory pressures between open mouth rigid and compliant soft palate airway conditions (compliant minus rigid). The results are for natural breathing. Error bars correspond to an uncertainty of 2 standard deviations.

Similar to natural breathing at peak inspiration (section 8.2), the difference in pressures between compliant and rigid airway conditions must be due to flow induced movement of the soft palate, which in turn will have an effect on the flow.

As a reminder to the reader, during expiration, the air flow is expired from the trachea. Approximately around the oropharynx, the flow partitions into the two paths, oral and nasal passages, and is expired from the airway. This is illustrated in Figure 72.

Figure 72. Airflow schematic during natural breathing peak expiration

Hypothesis I- The compliant soft palate tends toward the anterior, increasing the cross-sectional area of the velopharynx. This is the same hypothesis as hypothesis I for inspiration with natural breathing (section 8.2); hence a similar mechanism causes the difference in airway pressures for a compliant soft palate condition, only that flow travels in the outward, expiratory direction. A widening of the velopharynx will consequently cause a narrowing of the oral-to-pharynx passage, and hence causes a shift in resistance for the nasal and oral passages. The resistance shift in the compliant airway will affect the partitioning of flow between the nasal and oral passages, as air will prefer to travel via path of least resistance. Figure 73 summarises the expired flow rates from the nose and mouth for both airway conditions. It can be seen that the compliant airway has approximately 1.0 ± 0.6 L/min more than rigid in the nasal passage and hence a lower flow rate for the oral passage. A greater flow rate in the upper pharynx will result in greater pressures in the nasopharynx and velopharynx regions, as, once past the soft palate, the resistance for the remainder of the distance to atmosphere is the same for rigid and compliant models. Resistance being the same, higher pressures must indicate higher flow rates. This can explain why, relative to the rigid airway, the compliant airway has greater pressures in the upper pharynx, and lower pressures in the oral cavity. Hypothesis I is consistent with the data.

Figure 73. Flow rates in the rigid and compliant soft palate airway during natural breathing at peak expiration and absolute difference between the two. Error bars correspond to an uncertainty of 2 standard deviations.

Hypothesis II – The alternative hypothesis is that the soft palate tends toward the posterior on expiration causing a reduction in cross-sectional area at the velopharynx. As a consequence, this will increase the cross-sectional area of the oral-to-pharynx passage. The resistance to flow in the compliant airway will increase in the nasal passage and decrease in the oral passage, causing less flow to exit via the nasal cavity and vice versa for the oral cavity. This will result in lower pressures in the upper pharynx airway pressures and greater pressures in the oral cavity of the compliant airway compared to the rigid airway. The consequences of this hypothesis are not consistent with the results from the peak expiratory pressures (Figure 70) and the air flow distribution (Figure 73); therefore hypothesis II is not able to explain the effects of compliance in the upper pharynx and the oral cavity.

Lower Pharynx

Similar to the peak inspiratory during natural breathing (Section 8.2), the lower pharynx region has the most significant difference in peak expiratory pressures when comparing between rigid and compliant soft palate conditions. In the regions between the oropharynx and trachea, the compliant airway pressures are greater than the corresponding rigid pressures by 1.9 ± 0.9 Pa to 2.4 ± 0.6 Pa. This can be explained with the same mechanisms for inspiration during natural breathing, only that flow is now moving in the opposite direction. A constriction to flow occurs for either the nasal passage or oral passage, depending on the hypothesis. A pressure loss will occur across this constriction causing the upstream regions, which in the case of expiration is the lower pharynx, to increase in pressure. This can explain why the lower pharynx is affected by compliance even though it is distal to the soft palate. Taking this pressure loss into account, it is consistent with either hypothesis as both propose a constriction in either of the oral or nasal passages.

Similar to inspiration at natural breathing, the peak expiratory pressures in a closed mouth rigid condition exceeded those measured in both open mouth conditions (Figure 70). This is consistent with the findings by Groves and Tobin (2007) who measured airway pressures in the oropharynx during mouth open and mouth closed breathing. This is due to the increase in resistance of a closed mouth breathing condition. A similar outcome would be expected for a closed nose condition, where air is breathed exclusively through the mouth. The resistance for each airway condition during expiration is summarised in Table 15. It can be seen that the rigid, closed mouth airway has a resistance over twice as great as the rigid open mouth. The compliant open mouth airway also has a higher resistance than rigid open mouth airway, although not to the same extent as the closed mouth. Resistance is non-linear with area, hence increasing area of one passage will not compensate for narrowing the other by the same amount, and hence why there is a net increase. This can explain how soft palate compliance affects resistance and hence how it affects the peak expiratory pressures globally, including the regions distal to the soft palate, such as the lower pharynx.

Table 15. Airway resistance at expiration for different conditions

Airway Condition	Resistance (Pa min L⁻¹)
Rigid Open Mouth	0.99 ± 0.04
Compliant Open Mouth	1.15 ± 0.03
Rigid Closed Mouth	2.41 ± 0.06

To conclude this section, the results and hypothesised mechanisms for both natural breathing phases are summarised in Table 16.

Table 16. Summary of results

Breath	Phase	Results (compliant relative to rigid)	Hypothesis
Natural Breath	Inspiration	<u>Pressures</u> : More negative in the pharynx; less negative in the oral cavity. <u>Flow rate</u> : More flow in the nasal passage; less flow in the oral cavity	Anterior soft palate movement → nasal passage resistance decreases, oral passage resistance increases. → flow preference shift → Greater flow on inspiration = more negative pressures; vice versa for lower flow
	Expiration	<u>Pressures</u> : More positive in the pharynx; less positive in the oral cavity. <u>Flow rate</u> : More flow in the nasal passage; less flow in the oral cavity	Anterior soft palate movement → nasal passage resistance decreases, oral passage resistance increases → flow preference shift → greater flow on expiration = more positive pressures, and vice versa for lower flow

8.4 NHFT at 30 L/min with a Compliant Soft Palate: Inspiration

Figure 74 summarises the peak inspiratory pressures in the along the pharynx of the open mouth rigid and compliant airway conditions. Figure 75 shows the difference between open mouth rigid and compliant airway pressures at peak inspiration. It should be noted, that the oral cavity results were neglected in the NHFT sections as these regions had a large amount of noise and useful information could not be extracted. The following observations can be made between open mouth rigid and compliant airways from the pressure results:

1. In the nasopharynx (13 and 14) the compliant pressures are similar and within uncertainty to the corresponding rigid pressures. There is no statistically significant difference in pressures between rigid and compliant soft palate airway conditions at these regions.
2. At the velopharynx (tap 17) the compliant airway has a greater pressure than the rigid airway by 3.1 ± 1.9 Pa. This is the most significant difference between rigid and compliant airways.
3. In the lower pharynx region (taps 18, 23, 24, 28) there is little to no difference between rigid and compliant pressures. The oropharynx (tap 18) and laryngopharynx (tap 23) pressure of the compliant airway are lower than their corresponding rigid pressures by 1.4 ± 1.1 Pa and 1.1 ± 0.8 Pa, respectively. At the larynx (tap 23) and the trachea (tap 28) the rigid and compliant pressures are similar and within uncertainty, indicating no statistical significance between the two conditions.

Figure 74. Peak inspiratory static pressures measured along the airway during NHFT assisted breathing at 30 L/min. This shows pressure measurements for an open mouth rigid and compliant soft palate airway condition. Error bars correspond to an uncertainty of 2 standard deviations.

Figure 75. Difference between rigid and compliant pressures on peak inspiration (compliant minus rigid). The error bars correspond to an uncertainty of 2 standard deviations

From the results it is clear that the effects of compliance are limited to the areas local to the soft palate. The flow rate distribution between oral cavity and nasal cavity for the compliant and rigid airway conditions is summarised in Figure 76. It can be seen that there is no statistically significant difference in the partitioning of flow rate between the two airway conditions. This confirms that any effects due to soft palate compliance are purely local to the site of compliance.

Figure 76. Flow distribution in the rigid and compliant soft palate condition airway during inspiration with NHFT at 30 L/min. Positive direction corresponds to flow entering the airway, negative directions corresponds to flow leaving the airway. Also shows absolute difference between rigid and compliant flow rate. Error bars correspond to an uncertainty of 2 standard deviations.

It should be remembered that during inspiration with NHFT at 30 L/min there are three paths for the flow to consider Figure 77:

1. Cannula flow enters the nose, a portion of this flow turns around and leaves through the leak area.
2. A portion of the cannula flow persists through the nasal passage to meet part of the inspiratory demand.
3. Air is inspired through the oral cavity to meet the remainder of the inspiratory demand.

Figure 77. Air flow schematic illustrating flow distribution during inspiration with NHFT at 30 L/min

Hypothesis I – Soft palate moves toward the anterior of the airway causing an increase in cross-sectional area in the velopharyngeal airway channel. Figure 78 illustrates the hypothesised soft palate deformation. An increase in cross-sectional area of this region will cause a deceleration of the flow and an increase in pressure, as per the Bernoulli Effect. Anterior motion of the soft palate will also decrease cross-sectional area of the oral-to-pharynx passage, causing a constriction to flow entering via the mouth. The small decrease in pressure seen in the oropharynx and the laryngopharynx, which are downstream to the oral cavity, may be caused by a pressure drop from the said constriction.

Figure 78. Diagram showing a mid-sagittal cross-section of the airway to illustrate hypothesis I. The yellow soft palate represents the position for a rigid condition, and the super-imposed, pink soft palate represents the compliant condition with the motion described for hypothesis I. The arrows illustrate the direction of air flow (blue = atmospheric air, red = NHFT air).

Hypothesis II – The alternative hypothesis suggests that the uvula of the soft palate, which is located just below the velopharynx, slumps toward the posterior of the airway causing a decrease in cross-sectional area of the region immediately inferior to the velopharynx. It is assumed that the uvula would be susceptible to gravity induced slumping, as mechanically, it is analogous to a cantilever due to its free end boundary condition as it is not fixed to the walls of the airway. Figure 79 shows the soft palate insert in the airway, obtained from the CAD model (left) and an illustration of the proposed soft palate slumping in the compliant airway (right). This hypothesis indicates that the constriction caused by the uvula, which is immediately downstream of the velopharynx, will increase the resistance to flow at the velopharynx and hence it will increase the corresponding velopharyngeal static pressure due to viscous losses. A pressure loss will occur across this constriction, and can explain why the pressures at the oropharynx and laryngopharynx of the compliant airway are lower than the rigid airway.

Figure 79. Diagram coronal section view of the soft palate insert from the posterior direction of the CAD model (left) and a schematic of the mid-sagittal cross-section to illustrate hypothesis II (right). In the right image, the yellow soft palate represents the position for a rigid condition, and the super-imposed, pink soft palate represents the compliant condition with the motion described for hypothesis II. The arrows illustrate the direction of air flow (blue = atmospheric air, red = NHFT air).

Hypothesis II suggests that the difference between rigid and compliant airways is due to the posterior slumping of the uvula, and purely due to gravity. However, during natural breathing inspiration, it was concluded that flow induced effects caused anterior motion of the soft palate. With the greater pressure generation by NHFT it would be expected that the distending effects of the therapy should also push the soft palate anteriorly. This begs the question: How can slumping, a gravitational induced mechanism, occur during NHFT inspiration but not for natural inspiration? Perhaps the slumping of the uvula is initiated by the therapy jet. A third hypothesis is made which elaborates on hypothesis II and takes into account the possible distending effects of the therapy.

Hypothesis III- Although uvula slumping may be a consequence due to gravitational effects, perhaps it is also promoted by NHFT. The cannula flow causes distending effects on the compliant soft palate around the velopharynx region. The force exerted by the pressure pushes the soft palate, causing it to bulge anteriorly, however there is a reactive force at the free end of the soft palate, causing the uvula to deflect posteriorly (see Figure 80). Hence the constriction at the uvula region will increase the resistance of the upstream velopharynx, causing the static pressure to increase, as described for hypothesis II.

Figure 80. Diagram showing a mid-sagittal cross-section of the airway to illustrate hypothesis III. The yellow soft palate represents the position for a rigid condition, and the super-imposed, pink soft palate represents the compliant condition with the motion described for hypothesis III. The arrows illustrate the direction of air flow (blue = atmospheric air, red = NHFT air).

From all the tested breathing cases, inspiration with NHFT at 30 L/min is minimally affected by soft palate compliance. It is the only case not to undergo a global change in pressures, unlike the previously discussed natural breathing and the forthcoming expiratory phase and NHFT 60 L/min. It is not entirely clear why only there is only a difference local to the site of compliance. In the remaining sections, compliance of the soft palate affects causes a global change in airway pressures, and alters how flow is partitioned between oral and nasal passages. In the current case, the oral and nasal flows are consistent between rigid and complaint airway conditions, and pressures only at the velopharynx and oropharynx are affected. The three suggested hypotheses speculate how this may be caused by the soft palate motion, however it is unclear why this is limited to velopharynx only. Given that compliance only causes a statistically significant change in pressure at one location, none of the three hypotheses can be ruled out at this stage.

To scrutinize the slumping hypothesis, compliant airway pressures must be assessed with the airway flipped 180° along its longitudinal axis so that the airway is orientated in a prone, face down position. This study was carried out and is discussed later in section 8.8 of this chapter.

The results and hypothesised mechanisms thus far are summarised in Table 17.

Table 17. Summary of results

Breath	Phase	Results (compliant relative to rigid)	Hypothesis
Natural Breath	Inspiration	<p><u>Pressures</u>: More negative in the pharynx; less negative in the oral cavity.</p> <p><u>Flow rate</u>: More flow in the nasal passage; less flow in the oral cavity</p>	<p>Anterior soft palate movement → nasal passage resistance decreases, oral passage resistance increases. → flow preference shift → Greater flow on inspiration = more negative pressures; vice versa for lower flow</p>
	Expiration	<p><u>Pressures</u>: More positive in the pharynx; less positive in the oral cavity.</p> <p><u>Flow rate</u>: More flow in the nasal passage; less flow in the oral cavity.</p>	<p>Anterior soft palate movement → nasal passage resistance decreases, oral passage resistance increases → flow preference shift → greater flow on expiration = more positive pressures, and vice versa for lower flow</p>
NHFT 30 L/min	Inspiration	<p><u>Pressures</u>: Greater pressure at velopharynx only. All remaining regions have unchanged pressure.</p> <p><u>Flow rate</u>: No change between rigid and compliant.</p>	<p><u>Hypothesis I</u>: anterior soft palate movement → Deceleration of flow, increase in pressure (Bernoulli's law) <u>Hypothesis II</u>: uvula posterior slumping → Increase in resistance at the velopharynx <u>Hypothesis III</u>: Same as hypothesis II, with anterior bulging at the velopharynx region. Note: none of these can be ruled out on the evidence to hand.</p>

8.5 Compliant Soft Palate NHFT 30 L/min: Expiration

The profile for peak expiratory pressures along the airway are summarised in Figure 81, however, oral cavity pressures are not shown due to noise. The graph shows the peak expiratory pressures for the open mouth airway with rigid and compliant soft palate conditions. When comparing the open mouth rigid and compliant airway results, the compliant airway experiences a global increase in pressures. The differences between open mouth rigid and compliant airway pressure ranges from 4.9 ± 3.7 Pa at the nasopharynx (tap 13) to 6.1 ± 3.4 Pa at the trachea

(tap 28). These are summarised in Figure 82. During expiration with NHFT at 30 L/min, endoscopic video recording showed noticeable motion of the compliant soft palate, which tended toward the anterior of the airway.

Figure 81. Peak expiratory gauge pressures measured along the airway during NHFT assisted breathing at 30 L/min. This shows pressure measurements for an open mouth rigid and compliant soft palate airway condition. Error bars correspond to an uncertainty of 2 standard deviations.

Figure 82. Pressure difference between compliant and rigid soft palate conditions on peak expiration (compliant minus rigid) with NHFT 30 L/min. The error bars correspond to an uncertainty of 2 standard deviations.

It should be remembered how the air flow is partitioned during expiration with NHFT at 30 L/min. As shown with the flow measurements (Chapter 6) and with PIV data by Spence (2011) (Figure 83), during expiration with NHFT at 30 L/min the flow in the airway is distributed as follows:

1. Expired stream of air from the tracheal end travels along the pharynx and exits the airway via the mouth.
2. A portion of cannula air entering the nasal cavity will turn and leave the airway via the leak area between the nostrils and cannula.
3. The remainder of the cannula air will persist through the nasal cavity, enter the upper pharynx, and immediately leave the airway via the mouth.

Figure 83. PIV data for open mouth breathing at peak expiration with NHFT 30 L/min. Adapted from Spence (2011)

Figure 84. Airflow schematic during NHFT 30 L/min peak expiration

Figure 85 summarises the partitioning of air flow in the rigid and compliant airway models during expiration with NHFT at 30 L/min. It can be seen that in the compliant airway, there is more flow exiting via the leak area than in the rigid airway, by 2.2 ± 0.7 L/min. Hence there is less airflow travelling through the nasal passage of the compliant airway, and ultimately, less total expired flow during peak expiration.

Figure 85. Flow distribution in the rigid and compliant soft palate condition airway during expiration with NHFT at 30 L/min. Positive direction corresponds to flow entering the airway, negative directions corresponds to flow entering the airway. Error bars correspond to an uncertainty of 2 standard deviations.

As seen in the PIV data by Spence (2011) (Figure 83), there are two opposing streams during peak expiration with NHFT 30 L/min. The cannula air, and the expired stream from the tracheal end meet as they enter the oral cavity via the oral-to-pharyngeal passage. A large generation in pressure would be expected as the flows decelerate and curve around the soft palate. It is thought that the force exerted from the pressure of the flow causes the distending effects on the soft palate and can explain the anterior motion observed by the endoscopic camera.

The anterior motion of the soft palate, which was observed and confirmed by the endoscopic imaging, will cause an increase in cross-sectional area of the velopharynx and consequently will reduce the cross-sectional area of the oral-to-pharynx passage (see Figure 86). The widening of the velopharynx reduces the resistance of the upstream regions in the nasal passage, and should allow for a greater portion cannula air to proceed into the compliant airway; however, as shown in Figure 85, the compliant airway actually has more nasal leak, and hence less cannula air travelling via the nasal passage. The narrowing of the oral-to-pharynx passage that occurs, acts as a restriction to both the cannula air from the nasal passage and the expired air from the trachea end, as both of these streams meet in the oral cavity. Hence, the net resistance of the compliant airway must increase, which can explain the reduction of cannula flow entering into the compliant airway and the global increase in peak expiratory pressures.

In the compliant airway, more nasal leak means that a greater portion of cannula air that enters the nasal passage, will reverse to leave through the leak area, thus decelerating. This will produce higher static pressures in the compliant airway.

Figure 86. Diagram showing a mid-sagittal cross-section of the airway. The yellow soft palate represents the position for a rigid condition, and the super-imposed, pink soft palate represents the compliant condition with the anterior motion. The arrows illustrate the direction of air flow.

Table 18. Summary of results

Breath	Phase	Results (compliant relative to rigid)	Hypothesis
Natural Breath	Inspiration	<u>Pressures</u> : More negative in the pharynx; less negative in the oral cavity. <u>Flow rate</u> : More flow in the nasal passage; less flow in the oral cavity	Anterior soft palate movement → nasal passage resistance decreases, oral passage resistance increases. → flow preference shift → Greater flow on inspiration = more negative pressures; vice versa for lower flow
	Expiration	<u>Pressures</u> : More positive in the pharynx; less positive in the oral cavity. <u>Flow rate</u> : More flow in the nasal passage; less flow in the oral cavity	Anterior soft palate movement → nasal passage resistance decreases, oral passage resistance increases → flow preference shift → greater flow on expiration = more positive pressures, and vice versa for lower flow
NHFT 30 L/min	Inspiration	<u>Pressures</u> : Greater pressure at velopharynx only. All remaining regions have unchanged pressure <u>Flow rate</u> : No change between rigid and complaint	<u>Hypothesis I</u> : anterior SP movement → Deceleration of flow, increase in pressure (Bernoulli's law) <u>Hypothesis II</u> : uvula posterior slumping → Increase in resistance at the velopharynx <u>Hypothesis III</u> : Same as hypothesis II, with anterior bulging at the velopharynx region. Note: none of these can be ruled out on the evidence to hand.
	Expiration	<u>Pressure</u> : global increase in the pharynx <u>Flow rate</u> : more leak, less cannula flow in the airway. Endoscope shows anterior movement	Anterior motion causes constriction to the oral-to-pharynx passage → Resistance increase to all exiting via oral cavity, hence global pressure increase

8.6 NHFT 60 L/min with a Compliant Soft Palate: Inspiration

Figure 87 shows the profile of peak inspiratory pressures along the airway for the rigid and compliant soft palate airway conditions, however the pressures at the oral cavity are not shown due to noise. It is clear that in open mouth breathing, the compliant soft palate airway experiences greater peak pressures compared to the rigid airway, throughout all regions. Figure 88 shows the difference in pressure between open mouth rigid and compliant airway conditions. These conclusions cannot be made for the superior nasopharynx (tap 13) as the difference between compliant and rigid is less than the associated uncertainty; however, for the remainder of the regions, the difference

between compliant and rigid inspiratory pressures ranges from 7.0 ± 5.2 Pa to 13.2 ± 4.7 Pa, and at the velopharynx, the greatest difference of 18.2 ± 6.7 occurs.

Figure 87. Peak inspiratory pressures along the airway for NHFT 60 L/min. The results are shown for an airway with a rigid and compliant soft palate condition. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 88. Pressure difference between compliant and rigid soft palate conditions on peak inspiration with NHFT at 60 L/min (compliant – rigid). The error bars correspond to an uncertainty of 2 standard deviations.

As a reminder to the reader, during expiration with NHFT at 60 L/min there are three possible pathways for the cannula flow as it enters via the nostrils:

1. Turn and exit through the nostril (nasal leak rate).
2. Travel into the nasal cavity, pharynx and through the tracheal end to meet inspiratory demand.
3. Travel into the nasal cavity and at some point within the pharynx turn and exit via the oral cavity.

The outward flow from the mouth (pathway 3) exists the airway during inspiration because the net volume of cannula air that enters the nasal cavity exceeds that of the inspiratory demand, and hence must leave via the oral cavity. This is true even after a portion cannula air leaves the airway due to the nasal leak rate. By laws of mass conservation, the net nasal passage flow is the sum of the outward oral flow and the inspiratory demand (Figure 89).

Figure 89. Schematic illustrating the direction of air flow during inspiration with NHFT at 60 L/min.

Figure 90. Flow rate partitioning in rigid and compliant soft palate condition airway during inspiration with NHFT at 60 L/min. Negative flow rates indicate that flow is travelling outward from the airway. The error bars correspond to an uncertainty of 2 standard deviations.

Hypothesis I - The hypothesis is made that the soft palate is pushed toward the anterior of the airway, causing an increase of the cross-sectional area of the velopharynx, due to the distending effects from the continuous positive airway pressure (CPAP) that the therapy provides (see Figure 91). This will reduce the resistance to the flow entering the nasal passage; however, as a consequence there is a narrowing of the oral-to-pharyngeal passage which restricts the outward, excess air that leaves the airway via the mouth, and hence will increase the resistance of the airway. The outward oral flow in NHFT 60 L/min inspiration makes this case similar to the mechanisms described for expiration at NHFT with 30 L/min (section 8.5). The oral and nasal flow rates are summarised in Figure 90 above, where the compliant airway has a greater nasal leak rate than that of the rigid airway by 2.3 ± 1.5 L/min and thus less cannula flow enters the nasal passage of the compliant airway. Because of the resistance at the oral-to-pharynx passage of the compliant airway, a greater portion of the cannula flow turns and leaves the nasal cavity via the leak area, causing a deceleration of flow and an increase in pressures. The resistance of oral-to-pharynx passage causes viscous losses to the upstream flow, hence raises the pressures globally throughout the compliant airway.

Figure 91. Diagram showing a mid-sagittal cross-section of the airway. The yellow soft palate represents the position for a rigid condition, and the super-imposed, pink soft palate represents the compliant condition with hypothesis I. The arrows illustrate the direction of air flow.

Hypothesis II- An alternative hypothesis is added to consider uvula slumping, which is a hypothesised mechanism for NHFT 30 L/min inspiration. If soft palate slumping occurs during NHFT 30 L/min inspiration, it is possible that it may also occur for NHFT 60 L/min. The distending effects of the therapy push the soft palate body toward the anterior, however to a greater extent than the 30 L/min case, due to the higher therapy flow. This causes an anterior bulging, and causes a constriction in the oral-to-pharynx passage similar to what was described in the aforementioned hypothesis I, and can explain the global rise in pressure of the compliant airway. At the same time, there is a consequential posterior deflection of the uvula (see Figure 92). Looking back at Figure 88, the velopharynx has the most significant pressure difference when comparing between rigid and compliant. The posterior deflection of the uvula may increase the resistance at the upstream velopharynx, and hence can explain why this region experiences an increase in pressure for the compliant airway case.

Figure 92. Diagram showing a mid-sagittal cross-section of the airway. The yellow soft palate represents the position for a rigid condition, and the super-imposed, pink soft palate represents the compliant condition with hypothesis II. The arrows illustrate the direction of air flow.

Table 19. Summary of results

Breath	Phase	Results (compliant relative to rigid)	Hypothesis
Natural Breath	Inspiration	<p><u>Pressures</u>: More negative in the pharynx; less negative in the oral cavity.</p> <p><u>Flow rate</u>: More flow in the nasal passage; less flow in the oral cavity</p>	<p>Anterior soft palate movement → nasal passage resistance decreases, oral passage resistance increases. → flow preference shift → Greater flow on inspiration = more negative pressures; vice versa for lower flow</p>

NHFT 60 L/min	Inspiration	Global pressure increase in the pharynx	<p><u>Hypothesis I</u>: Anterior SP movement → Resistance increase to oral-to-pharynx passage, <u>Hypothesis II</u>: Uvula slump, soft palate bulging. → Resistance increase to oral-to-pharynx passage, Note: none of these can be ruled out on the evidence to hand.</p>

8.7 NHFT 60 L/min with a Compliant Soft Palate: Expiration

The case of expiration with NHFT at 60 L/min, a similar outcome occurs as in expiration with NHFT at 30 L/min, only to a larger extent as a greater therapy flow administered. That is to say, the peak expiratory pressures in the compliant soft palate airway exceed the corresponding pressures in the rigid airway, globally. The peak expiratory pressure profile along the different airway conditions is shown Figure 93 and the absolute differences between

compliant and rigid are shown in Figure 94. Endoscopic imaging showed that the soft palate moved toward the anterior at peak expiration. It can be said that this was a similar outcome to expiration with NHFT at 30 L/min, only with more pronounced results due to the greater level of therapy used. Therefore the same mechanisms are hypothesised to explain the difference in results between open mouth rigid and compliant airway conditions.

Figure 93. Peak expiratory pressures along compliant and rigid airway for NHFT assisted breathing at 60 L/min. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 94. Pressure difference between compliant and rigid soft palate conditions on peak expiration with NHFT at 60 L/min (compliant minus rigid). The error bars correspond to an uncertainty of 2 standard deviations.

Figure 95. Flow rate partitioning in rigid and compliant soft palate condition airway at peak expiration with NHFT at 60 L/min. Negative flow rates indicate that flow is travelling outward from the airway while positive flow rates indicate an inward flow. The error bars correspond to an uncertainty of 2 standard deviations.

Table 20. Summary of results

8.8 Supine vs Prone

The compliant airway was tested for in a ‘prone’ position, where the model was rotated 180° about its longitudinal to a face down orientation. This was to investigate any potential gravitational effects that may cause soft palate slumping. In the supine position, the effects of gravity may cause the compliant soft palate body to slump toward the posterior of the airway, and vice versa for the prone position. These gravity induced deformations may also affect breathing, hence it was desired to determine to what extent gravity affected the breathing.

8.8.1 Natural Breathing

The pressures results are summarised in Figure 96. It is quite clear that the peak airway pressures for supine and prone testing positions are similar and within uncertainty. It can be said that there is no difference between the compliant supine and prone positions at peak inspiration and peak expiration. Therefore the effects of gravity are neglected, and differences between rigid and compliant soft palate airway condition is purely due to flow induced effects.

Figure 96. Prone vs supine for a compliant soft palate airway condition during natural breathing. The error bars correspond to an uncertainty of 2 standard deviations

8.8.2 NHFT 30 L/min

Figure 97 summarises the peak airway pressures in compliant supine and prone testing positions during peak inspiration and peak expiration with NHFT at 30 L/min.

Figure 97. Prone vs supine for a compliant soft palate condition, and supine results for a rigid airway. Breathing with NHFT at 30 L/min. The error bars correspond to an uncertainty of two standard deviations.

It can be seen that during inspiration, the only difference between prone and supine positions of the compliant airway occurs at the velopharynx. The prone positioned airway has a lower velopharyngeal pressure than rigid airway, and for the supine positioned airway it is greater than rigid. This indicates that there is orientation dependent soft palate movement. It is assumed that the soft palate will slump in the direction of gravity, where in the supine position, the soft palate will tend toward the posterior and on prone it will tend toward the anterior. Assessing the previously made hypotheses, when the airway was tested in a supine position in section 8.4:

- Hypothesis I indicated an anterior motion of the soft palate, and local pressure change was caused by the Bernoulli Effect. Pure anterior motion of the soft palate occurred, however the supine vs prone study indicates that there must be some slumping involved in the mechanism.
- Hypothesis II indicated slumping of the uvula only (toward the posterior for supine).
- Hypothesis III, indicated posterior uvula slumping, which was consequently due to the reactive forces pushing the soft palate body toward the anterior.

Hypothesis I cannot be valid as it speculates that there is only anterior motion of the soft palate when the airway was tested in the supine position. Supine vs prone results confirm that there must be some gravitational induced effects, hence a supine position must have a posterior tending soft palate. Hypothesis I must be ruled out. Hypothesis II stated that slumping occurs purely due to gravitational effects; however, in natural breathing, there is no indication of gravitational effects, and soft palate slumping only occurs during NHFT, hence this must be instigated by the cannula flow. Therefore from the supine vs prone results, hypothesis III is the most likely explanation for the results, as it explains that the distending effects of the therapy cause anterior bulging of the soft palate around the velopharynx, and consequently induces uvula deflection in the direction of gravity (see Figure 98 (left)). The corresponding hypothesis is applied to the prone orientated compliant airway (see Figure 98 (right)), where the distending effects of the therapy push the soft palate toward the anterior, which is consistent with both supine and prone orientations. However, in the prone position, uvula slumps toward the anterior, which reduces the resistance at the upstream velopharynx, and hence why the prone positioned airway has lower velopharyngeal pressures.

Figure 98. Soft palate motion during inspiration with NHFT 30 L/min. Soft palate motion in the supine position (left) and the prone position (left) under the premise of hypothesis III. The yellow soft palate represents the position for a rigid condition, and the super-imposed, pink soft palate represents the compliant condition.

During expiration with NHFT at 30 L/min, there is no statistically significant difference between supine and prone orientated compliant airways. The peak pressures for these positions are similar to one another and within uncertainty, which must mean that the soft palate behaves the same way for both orientations at expiration. With the endoscope it was observed that the soft palate would tend toward the anterior on expiration. The cannula air and the opposing expired stream from the tracheal end meet as they enter the oral-to-pharynx passage, and a large pressure is generated, as a deceleration of the flow occurs. This exerts a force on the soft palate and causes it to move anteriorly. Although there is a clear difference between supine and prone on inspiration, with the hypothesis that in a supine orientation the uvula slumps posteriorly; it can be said that on expiration, the forces generated by the flow, exceed that of gravity and cause an anterior motion for both supine and prone. This can explain why the two orientations do not show a difference in pressure during peak expiration.

8.8.3 NHFT 60 L/min

The supine vs prone results are summarised in Figure 99, where pressure results are shown for both compliant airway orientations and the rigid airway. During inspiration, the only difference in peak pressures between supine and prone position occurs in the velopharynx, while the remainder of the regions, such as the nasopharynx and the lower pharynx have the same peak airway pressures regardless of testing position. Therefore there are consistent flow induced effects in the compliant airway, but there is also an orientation dependent effect at the velopharynx.

Figure 99. Prone vs supine for compliant soft palate condition, and supine results for a rigid airway. Breathing with NHFT at 60 L/min. The error bars correspond to an uncertainty of 2 standard deviations.

Similar to NHFT 30 L/min inspiration, there is a clear difference between supine and prone positions at the velopharynx only. Supine has greater pressures than rigid and prone has lower pressures than rigid. It can be assumed that there is uvula slumping which tends toward the direction of gravity, and that there are orientation dependent effects at the velopharynx only. However, given that the pressures in all remaining regions are consistent in the compliant airway, regardless of orientation, there must be consistent flow induced effects in the compliant airway. The two hypotheses that were made for this mode of breathing with in a supine position were as follows:

- Hypothesis I: anterior motion of the soft palate body, widening the velopharyngeal cross-sectional area, and consequently constricting the oral-to-pharynx region.
- Hypothesis II: NHFT causes anterior bulging of the soft palate at the velopharynx which constricts the oral-to-pharynx passage, and the uvula deflected toward the posterior.

For the same reasons as described for NHFT 30 L/min inspiration, hypothesis I can be ruled out. Hypothesis II explains that the CPAP from the therapy pushes the soft palate body toward the anterior, causing a bulge which constricts the oral-to-pharynx passage, hence causing the global increase on airway pressures, relative to rigid, as described previously in section 8.6. This part of the soft palate motion is consistent with supine and prone positions, hence all airway regions, with the exception of the velopharynx, experience an increase in pressures. However, depending on prone or supine position, there is uvula deflection in the direction of gravity. In the supine position, uvula tends posteriorly, which will increase the pressure at the velopharynx, with respect to rigid; and in the prone position, uvula tends toward anterior direction causing a decrease in resistance at the velopharynx and hence decrease in this regions' pressure. The hypothesised soft palate position is illustrated for supine and prone positions in Figure 100.

Figure 100. Hypothesis II for NHFT 60 L/min inspiration with a compliant soft palate. This shows the soft palate motion for a supine position (left) and prone position (right).

During expiration with NHFT at 60 L/min, there is no difference between supine and prone positions for the compliant airway. This can be explained with the same reasons as the supine vs prone case for expiration with NHFT at 30 L/min.

It should be noted that for the supine and prone position tests, if any other internal component is loose, it will move as the airway orientation is changed. This could cause some difference in results which is not due to the soft palate motion only.

8.9 Conclusion

The results and the hypothesised mechanisms for each breathing mode are summarised in Table 21. The supine vs prone results have been taken into account to explain the effect of soft palate compliance with the most likely hypothesis.

Table 21. Summary of results for the compliant soft palate pressure tests

9 Pressure Test: Compliant Tongue

9.1 Introduction

The following section compares the pressure measurements carried out on the airway model with a compliant tongue. The results are summarised by the presenting the mean pressure values measured at the posterior taps along each region in the pharynx of the airway (Table 22), similar to the soft palate results.

Table 22. A summary of the regions and tap locations used to present results in the current section

	Abbreviation	Tap Location
Superior Nasopharynx	S NP	13
Inferior Nasopharynx	I NP	14
Velopharynx	VP	17
Oropharynx	OP	18
Laryngopharynx	LP	23
Larynx	LP	24
Trachea	Tr	28

9.2 Results

9.2.1 Natural Breathing

There is no statistically significant difference between rigid and compliant tongue conditions during natural breathing. The peak expiratory and inspiratory pressures with a compliant tongue condition resemble the pressures experienced by the rigid airway for each corresponding tap (Figure 101). The differences between the rigid and compliant mean peak pressures that occur in the pharynx are shown in Figure 102 and these are all below 1 Pa. The uncertainties associated with each rigid vs compliant pressure differences are clearly greater than the differences themselves. This indicates that there is no appreciable distinction in airway pressures between a rigid and compliant tongue airway conditions during natural breathing.

Figure 101. Summary of mean peak expiratory and inspiratory pressures during natural breathing for rigid and compliant tongue conditions. The peak pressures shown correspond to the tap locations in the pharynx. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 102. Differences in peak airway pressures between rigid and compliant tongue conditions during natural breathing.

9.2.2 NHFT 30 L/min

With NHFT assisted breathing at 30 L/min, a similar outcome occurs as for natural breathing. There is no difference in peak airway pressures between rigid and compliant tongue conditions. The peak pressure profile along the airway model is shown in Figure 103. There is good resemblance between rigid and compliant tongue conditions for the corresponding peak pressures at each tap. Small deviations between rigid and compliant pressures can be seen on inspiration for taps 17 and 28, however the values are within range of uncertainty. Figure 104 shows that peak pressure differences between rigid and compliant are below 1.5 Pa and they less than their associated uncertainties. Therefore, there is no measureable difference between the peak pressures experienced in the rigid and compliant tongue conditions

Figure 103. Summary of mean peak expiratory and inspiratory pressures during NHFT 30 L/min assisted breathing for rigid and compliant tongue conditions. The peak pressures shown correspond to the tap locations in the pharynx. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 104. Difference in peak airway pressures between rigid and compliant tongue conditions during NHFT assisted breathing at 30 L/min. error bars correspond to an uncertainty of 2 standard deviations.

9.2.3 NHFT 60 L/min

Breathing with NHFT at 60 L/min yields the same results as for the previous breathing cases. There is no difference in airway pressures between rigid and compliant tongue. Figure 105 shows that rigid and compliant peak pressures are the same and within uncertainty. The difference between the peak pressures in the pharynx are summarised in Figure 106. These values lie under 2 Pa and they are less than their associated uncertainties. Therefore it can be concluded that there is no significant difference between rigid and tongue conditions during NHFT 60 L/min assisted breathing.

Figure 105. Summary of mean peak expiratory and inspiratory pressures during NHFT 60 L/min assisted breathing for rigid and compliant tongue conditions. The peak pressures shown correspond to tap locations in the pharynx. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 106. Differences in peak airway pressures between rigid and compliant tongue conditions during NHFT assisted breathing at 60 L/min. Error bars correspond to an uncertainty of 2 standard deviations.

9.3 Discussion

The results from the experiment clearly show that there is no difference in airway pressures between rigid and compliant tongue airway conditions. This is true for natural and NHFT assisted breathing. It was originally hypothesised that compliant tissues were susceptible to elastic deformations induced by the forces generated by the air flow. This change in the geometry of the compliant structures can consequently alter the flow field in the airway and impact the resistance during breathing.

It cannot be determined whether deformation of the compliant tongue takes place, and to what extent. The model used in the experiment was limited to manometry measurements. The complicated airway geometry made it too difficult to successfully image the tongue with the endoscopic camera, and the resolution was too poor to identify any possible small changes in the tongue geometry. However, because the pressure patterns between rigid and compliant are consistent, the pattern of the flow field must also remain consistent. Hence the deduction can be made that airway geometry must also remain consistent and no appreciable deformation of the tongue had occurred.

Studies into OSA demonstrated that in an affected airway, the compliant tongue undergoes deflection during natural breathing which increases the resistance of the airway compared to a rigid condition (Chouly et al., 2008; Liu et al., 2010; Rasani et al., 2011). However these were focussed on OSA and the idealized airway models that had an oropharyngeal posterior-anterior distance of approximately 1.8 mm. Rasani et al. (2011) demonstrated that in a healthy airway, with a typical oropharyngeal anterior-posterior displacement of 11 mm, the compliant tongue was subject to minimal changes and the airway resistance profile resembled that of a rigid condition. The airway model in the current study was based on a healthy geometry, with the oropharyngeal anterior-posterior distance of approximately 15 mm. The results by Rasani et al. (2011) support the findings of the current study for a compliant tongue airway during natural breathing.

There are no reported studies that compare compliant and rigid tongue conditions during NHFT assisted breathing, or for any other supplemental ventilation therapy. However *in vivo* studies by Schwab et al. (1996) determined that the application of nasal CPAP therapy on healthy airways had insignificant effect on the shape of the tongue, when compared to natural breathing. This was carried out with CPAP levels up to 15 cm H₂O. Although the current project employed NHFT, it is said that CPAP is one of the benefits of the therapy provided that the cannula flow rate is high enough. The greatest pressure recorded in the current airway model was approximately 180 Pa in the nasopharynx (with 60 L/min flowrate), which was less than half of the lowest level at CPAP applied by Schwab et al. (1996), at approximately 500 Pa (5 cm H₂O). Since Rasani et al. (2011) found that there was no change

between compliant and rigid tongue conditions for natural breathing, and Schwab et al. (1996) concluded that there was no difference in tongue shape between natural breathing and CPAP assisted breathing, connecting these two statements, it can be said that there is no change between compliant and rigid tongue conditions for all levels of therapy.

This study was representative of a single person, and therefore it cannot be said that tongue compliance will not affect breathing in a healthy airway. Variation in airway anatomy between different people may produce different results. As mentioned previously in the discussion that tongue compliance will have minimal effects on breathing for a posterior-anterior distance of 11 mm. Although this is typical for a healthy airway, this value can vary between people, and for smaller anterior-posterior distances, tongue compliance may affect breathing pressures. The effects of tongue compliance was also tested for an open mouth airway condition only. During closed mouth breathing, airway resistance increases and the peak pressures significantly increase in magnitude. It is possible that these may be great enough to cause deformation of the compliant tongue, therefore the conclusion made in this study, that there is no difference between rigid and compliant tongue airway conditions, can only be stated for an open mouth breathing and is not yet known for a closed mouth condition.

The geometry of the tongue insert was truncated on the sagittal sides, as the information for the entire shape was lost in the noise of the CT scan. However, the tongue surface which composed part of the airway passage in the oropharynx and oral cavity, was included in the insert design. The truncated sagittal sides were never exposed to airflow, so it is unlikely that they would affect the flow field. The compliant tongue insert was also made from a single material composition and was assumed to be a homogenous structure. In reality the tongue is comprised of several intrinsic and extrinsic muscles and likely to vary in stiffness. The contrast of the CT scans used to model the tongue made it difficult to distinguish between the different tissue layers, hence it was modelled as single structure for simplicity. Reported tongue elasticity in literature was also limited, therefore a single value was used. It is unknown as to what extent the tongue compliance may vary between the tissue layers; but given that in the current study there was no indication that a uniformly compliant tongue showed a difference, it is unlikely that incorporating multiple tissue layers would change results, unless the deeper tissues were of significantly lower compliance (less than 7.7 kPa).

The tongue is an airway dilator and during respiration there are small involuntary muscle movements. This is to maintain airway patency during breathing. In reality, the tongue would undergo small geometric changes, and changes to the stiffness, as muscles in the structure would activate and change the muscle tone. The current project simulated a static tongue as muscular motions were not replicated, and the stiffness of the material was held

constant. However, the purpose of the project was to investigate the passive movements of the tongue induced by air flow during respiration, and muscle activity was neglected in replicating a compliant airway.

9.4 Conclusion

The pressure experiments were carried out for an airway with a compliant tongue condition. Comparing the airway pressures for a rigid and compliant tongue airway condition, it was clear that there was no statistically significant difference between the two cases. This was consistent for all three tested breathing cases. This was also consistent with reported studies, who also found that in natural breathing, the tongue does not affect breathing, except for the case of OSA, where there is a difference in tongue geometry and properties compared to healthy subject. There are no reported studies on tongue compliance and NHFT breathing, however studies with CPAP therapy have shown that tongue experiences geometric changes when breathing was assisted with therapy.

10 Pressure Test: Compliant Vocal Folds

10.1 Introduction

The results in this section focus on the pressure tap locations in the laryngopharynx, larynx and trachea (taps 21, 22, 23, 24, 27, and 28), as these are the most local regions to the vocal folds (Figure 107 and Table 23). It should be noted that taps 25 and 26 were neglected, as difficulties in the casting procedure of the compliant vocal fold insert caused these taps to fill with silicone, and post-assembly drilling risked damaging the silicone.

Figure 107. A truncated diagram of the airway. This illustrates the pressure tap locations in the laryngopharynx, larynx and the trachea.

Table 23. Regions in close proximity to the vocal folds. The table shows the corresponding pressure tap number and abbreviation that are used to denote each region.

Region	Abbreviation	Tap numbers
Laryngopharynx	LP	21, 22, 23
Larynx	L	24, 27
Trachea	T	28

10.2 Results

10.2.1 Natural Breathing

The following section goes through the natural breathing results. The natural breathing condition refers to the breath experiments which simulated spontaneous breathing. In this condition NHFT was not applied and the cannula was completely removed. Figure 108 summarises the peak expiratory and inspiratory pressures at the tap locations in the nasal cavity and the pharynx of airway for both rigid and compliant cases. During natural breathing there was no significant difference in pressures between rigid and compliant conditions, globally in the airway. The error bars for the mean peak pressures correspond to an uncertainty of 2 standard deviations which were obtained from 100 individual breath cycles (Chapter 5).

Figure 108. Peak expiratory and inspiratory airway pressures throughout the pharynx during natural breathing. The plot shows a comparison between rigid and compliant vocal fold conditions. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 109 displays the mean transient pressure profile in the laryngopharynx, larynx and trachea for rigid and compliant. It can be seen that during a breath cycle the rigid and compliant pressure profiles are within range of uncertainty with one another. With the exception of tap 27, plots in Figure 109 show a small discrepancy between rigid and compliant conditions during inspiration and expiration phases. These correspond to peak pressure differences between rigid and compliant of 0.1 to 0.7 Pa, which corresponds to a relative difference from 0.2 to 2.5 %. The relative difference is defined as the percentage between the absolute difference and the peak to peak pressure value of rigid pressure measurement. However, the pressure profiles for rigid and compliant conditions at each tap are always within range of the uncertainty.

Figure 109. The mean transient pressure profiles during natural breathing. The measurements are shown in the laryngopharynx, larynx and trachea (taps 21, 22, 23, 24, 27 and 28) for rigid and compliant vocal fold conditions. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 110 summarises the absolute difference between compliant and rigid pressures at peak inspiration and peak expiration. The greatest difference between compliant and rigid during peak inspiration occurred in the laryngopharynx (tap 22) on peak inspiration and was found to be of 0.7 ± 1.4 Pa which corresponds to a relative difference of $2.5 \pm 5.1\%$. The differences between compliant and rigid pressures at peak expiration were all under 1 %, with the greatest difference occurring at the trachea (tap 28). This corresponded to an absolute difference of 0.4 ± 0.51 Pa. and a relative difference of $0.9 \pm 1.3 \%$. As mentioned previously, not only are the differences between rigid and compliant conditions small, they are also outweighed by their associated uncertainty, which in some cases is twice that of the absolute pressure difference. This concludes that vocal fold compliance does not affect pressure measurements during natural breathing.

Figure 110. Difference between rigid and compliant vocal fold airway pressures at peak expiration and peak inspiration during natural breathing. The error bars correspond to an uncertainty of 2 standard deviations.

10.2.2 NHFT at 30 L/min

The pressure measurements carried out for NHFT assisted breathing at 30 L/min resulted in the same outcome as for the natural breathing case. That is to say, there was no statistical significance in pressures between rigid and compliant vocal fold conditions. Figure 111 summarises the peak airway pressures for both rigid and compliant conditions throughout the nasal cavity and pharynx. It shows that rigid and compliant vocal fold pressures are similar and within range of uncertainty of each other.

Figure 111. Peak expiratory and inspiratory airway pressures throughout the pharynx during NHFT assisted breathing at 30 L/min. The plot shows a comparison between rigid and compliant vocal fold conditions. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 112 (see following page) shows the mean transient pressure profiles between compliant and rigid at each tap location for the laryngopharynx, larynx and tracheal regions. The rigid and compliant pressure profiles are within range of uncertainty with each other throughout the duration of the breath cycle. Figure 113 shows the absolute difference between the rigid and compliant peak pressures. These do not exceed 1.5 %, showing that only small differences occur between rigid and complaint. Also, the associated uncertainties of the pressure differences between rigid and compliant vocal fold cases are greater than the differences themselves. This concludes that there is no statistical evidence that vocal fold compliance has an effect on airway pressures during NHFT 30 L/min.

Figure 112. The mean transient pressure profiles during NHFT assisted breathing at 30 L/min. The measurements are shown in the laryngopharynx, larynx and trachea (taps 21, 22, 23, 24, 27 and 28) for rigid and compliant vocal fold conditions. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 113. Difference between rigid and compliant vocal fold airway pressures at peak expiration and peak inspiration during NHFT assisted breathing at 30 L/min. The error bars correspond to an uncertainty of 2 standard deviations.

10.2.3 NHFT 60 L/min

NHFT assisted breathing at 60 L/min yielded the same outcome as for the NHFT 30 L/min and natural breathing. No statistically significant differences in pressures between rigid and compliant vocal fold conditions. Figure 114 summarises the peak pressures in the nasal cavity and the pharynx. The results show that the peak pressures for rigid and compliant small differences can be seen, however the pressures are within the range of uncertainty.

Figure 114. Peak expiratory and inspiratory airway pressures throughout the pharynx during NHFT assisted breathing at 60 L/min. The plot shows a comparison between rigid and compliant vocal fold conditions. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 115 compares the rigid and compliant mean transient pressure profiles in the laryngopharynx, larynx and trachea. As seen in the natural and NHFT 30 L/min breathing cases, the rigid and compliant profiles align very well together, with small discrepancies that are within range of the uncertainty. There is no significant difference between rigid and compliant vocal fold conditions throughout the duration of the breath cycle.

Figure 115. The mean transient pressure profiles during NHFT assisted breathing at 60 L/min. The measurements are shown in the laryngopharynx, larynx and trachea (taps 21, 22, 23, 24, 27 and 28) for rigid and compliant vocal fold conditions. Error bars correspond to an uncertainty of 2 standard deviations.

Figure 116 shows the relative difference in peak pressures between rigid and compliant cases. During inspiration the greatest relative difference occurs in the larynx (tap 24) at 2.2 ± 4.3 %, corresponding to an absolute difference of 2.4 ± 4.8 Pa. The greatest relative difference at during peak expiration also occurs in the laryngopharynx (tap 22) at 1.2 ± 4.9 %, corresponding to 1.3 ± 5.4 Pa. Figure 116 shows that differences in peak pressures between rigid and compliant vocal folds are 2.1 % or less, and the uncertainty for these differences are greater than the differences themselves. This confirms that there is no significant difference between rigid and compliant vocal fold pressures during NHFT assisted breathing at 60 L/min.

Figure 116. Difference between rigid and compliant vocal fold airway pressures at peak expiration and peak inspiration during NHFT assisted breathing at 60 L/min. The error bars correspond to an uncertainty of 2 standard deviations.

10.3 Discussion

Prior to the experiment, the following hypotheses were made on how airway pressures will be affected due possible flow induced deformation of the compliant vocal folds:

- Hypothesis I: The static pressure of the airflow will induce wall deformation of the compliant vocal folds. Distending effects will occur on the vocal folds, causing the laryngeal passage to expand (or collapse with sub-atmospheric pressures). This will cause deceleration of flow and a further increase in static pressure (or acceleration of flow and decrease of static pressure in the case of collapse due to sub-atmospheric pressures). The continuous positive air pressure provided from the NHFT would increase these distending effects.

- Hypothesis II: The wall shear stress from the airflow acting on the surface and the compliant vocal folds will cause the silicone layer to deform parallel to the flow and deform in shear. It is difficult to determine how shear induced deformation would affect the breathing pressures.
- Hypothesis III: A combination of both I and II will contribute to changes in airway pressures between compliant and rigid vocal fold conditions.
- Hypothesis IV: Compliant vocal folds do not affect the airway pressures during natural and NHFT assisted breathing.

The results conclude that there was no statistically significant difference in airway pressures between rigid and compliant vocal folds for all three tested breathing cases. The relative differences of the peak airway pressures between rigid and compliant condition airway models were under 2.5 % and were always less than the associated uncertainty. The uncertainty of the pressure differences obtained from 2 standard deviations from the experiment reached as high as ± 6 % when taken relative to the peak to peak pressure of the mean rigid pressure profiles. It is possible that there were differences in airway pressures between rigid and compliant vocal fold conditions, however the experimental method may lack the accuracy to successfully detect these. Although the conclusion to this study states that there were no significant changes in airway pressures for rigid vs compliant, it cannot be ruled out that airflow does not induce deformation of the compliant vocal folds. It is possible that some deformation of the compliant vocal fold simulant may have occurred in the experiment, but was not sufficient enough to induce significant static pressure changes for the tested breathing conditions.

There are limited studies in literature that have investigated how the compliant vocal folds affect breathing. Kim et al. (2010) carried out a FSI on a compliant larynx for natural inspiration only and found significant deformation of the larynx of up to 0.9 mm. It was unclear what mode of deformation this was, and the study was not compared against rigid airway simulations, hence it is unknown how this deformation affected breathing. The pressure in the larynx observed by Kim et al. (2010) was approximately -80 Pa, which is significantly greater than the -28 Pa laryngeal pressure of the current study, measured during natural inspiration. This difference is most likely due to the difference in airway anatomy, as Kim et al. (2010) used a closed mouth airway, which tend to experiences greater peak expiratory pressures, and more negative peak inspiratory pressures during inspiration, compared to open mouth. They also used a greater peak inspiratory flow rate corresponded to 35 L/min, while the current study had a peak inspiratory flow 19.7 L/min, which would have affected the airway pressures.

The vocal folds are located in the larynx, and they are comprised of several tissue layers, which are anchored to cartilage. The tissue layers can be grouped by two categories corresponding to depth: the vocal fold cover, which are the superficial layers, and the vocal fold body, comprised of the vocal fold ligament, and the deeper vocal fold

muscle. In the current study, the compliant vocal fold insert was comprised of an outer rigid frame with an internal compliant surface which replicated the laryngeal airway passage. The compliant surface was comprised of 2.5 mm thick silicone layer, which simulated the compliance of the vocal fold cover and the superficial layer of the vocal fold ligament. The model in the current study neglected the deeper, compliant tissues, such as the deep lamina propria (vocal fold ligament) and vocal fold muscle, as these layers were part of the rigid frame insert. The CT scan that was used was limited as it did not have enough contrast to differentiate between tissue types and hence the histology of the deeper tissues could not be replicated in the insert. For more accurate replication of the tissue layer anatomy, a better quality medical scan is required which successfully captures the tissue histology. However, it was thought that simulating the vocal fold cover would be a sufficient enough representation of vocal fold compliance. The vocal fold body-cover concept theorizes that phonation occurs due to the vibration of the vocal fold cover. Though this study replicated vocal folds in a normal breathing state with no voice production, it was assumed that the vocal fold cover would be the most significant contributor to any potential compliant effects on the flow. Limiting the compliant vocal fold insert to the vocal fold cover also maintained simplicity in its design and manufacturing process.

The compliant vocal folds can be analogous to flow through a compliant tube. For expansion or collapse of the of the compliant tube to occur, the magnitude of pressure in the flow must exceed the atmospheric pressure outside the tube, and great enough to deform the compliant boundary. It is possible that the boundary condition of the vocal fold inserts' rigid frame prevented significant distending or collapsing effects on the compliant vocal fold as it acted as reinforcement to the compliant surface. Or perhaps flow induced deformation of the compliant vocal folds did occur, however the total volume of the compliant region was too small for geometrical distortions to significantly affect airway pressures. If the compliant boundary was extended to replicate the deeper tissues, there would be a greater compliant-layer-to-rigid-boundary thickness ratio, and there would be a greater volume of deformable region, which could possibly affect the flow with the aforementioned hypotheses. A phenomenon often seen in flows through complaint tubes is wave propagation. Previous studies, reported in literature, have investigated the effects of internal compliant surfaces in a rigid tube and found that for a greater compliant layer thickness, an increase in wall shear stress of the air flow would occur, and hence initiate unstable waves on the compliant surface (Clarke et al., 1970; Evrensel et al., 1993). The waves along the compliant lining were shown to increase resistance to the flow. There was no indication that such a phenomenon had occurred in the current study with the compliant vocal fold airway condition. However, it is possible that with a greater compliant region, which encompasses the deeper vocal fold tissues, this phenomenon may occur in a complaint vocal fold airway condition, causing an increase in airway resistance and hence an increase airway pressures.

It should be noted that the current study did not replicate an accurate model, only the passive properties of the muscles. In a real human airway, there is involuntary activity of the intrinsic muscles that maintain airway patency, and prevent collapse. Muscle activity would cause the tissue elasticity to vary, as a contracted muscle would have a greater stiffness than a relaxed muscle, hence vocal fold compliance would also vary over time. However, the purpose of this study was to investigate how the passive, flow induced motion of compliant tissues affected breathing. The elastic modulus of the compliant vocal fold insert was based on excised vocal fold tissue properties, reported by Chan et al. (2007), therefore it can be said that the compliant insert represented the vocal folds at their residual tension. Also studies have shown that during respiration, the muscle activity causes variation in glottal area, indicating that there are small actuations in the vocal folds (Scheinherr et al., 2015). Due to the limits of the model, these muscle induced anatomical changes in the vocal folds were not simulated. The model was a static, passive approximation of the compliant vocal fold airway condition.

It should be made clear that the anatomy of the vocal folds in the current airway model is specific to a single person. Anatomical variation between people always exists, and variations in vocal fold geometry may result in an increase in susceptibility to flow induced deformation. The rima glottidis, which is the airway space in the larynx, between the vocal folds, can vary in area between 131 mm^2 to 239 mm^2 in healthy airways (Rubinstein et al., 1989). For the airway model used in this research, this area was approximately 149 mm^2 . Vocal folds with a smaller glottal area would experience larger pressure drops across the glottis, which may result in significant compliant deformations. Therefore compliant vocal folds with variations in anatomy should be considered in future studies. Compliant vocal folds should also be considered for a closed mouth model, as it was been documented in the current study and previous studies that closed mouth airways have a greater resistance, and experience higher pressures. This may have a greater impact on compliance.

10.4 Conclusion

The pressure experiment was performed for the airway model with compliant vocal folds. The results yielded that there was no statistically significant difference in airway pressures between rigid and compliant vocal fold conditions, for all three tested breathing modes. It is possible that this was due to the limitations of the vocal fold model used, which only simulated the superficial compliant tissues. The vocal fold model should be further developed to replicate the deeper tissues in the larynx. It cannot be stated that compliance of the vocal folds does not affect natural and NHFT assisted breathing. It is also possible that the results are specific for the current airway model. Anatomical variation must be considered, and tests should be carried out on vocal folds with smaller glottal areas.

11 Capnography

11.1 Introduction

Capnography was performed on the airway model to investigate the influence compliant tissues have on CO_2 concentration in the airway. This was carried out for natural and NHFT assisted breathing. An example of an alveolar CO_2 concentration profile is shown in Figure 117. The profile can be divided into sections corresponding to the different phases of the respiration cycle. This goes as follows:

- A-B (Phase I) - Inspiration ends and expiration commences.
- B-C (Phase II) – The expired, CO_2 rich, alveolar gas mixes with the anatomical dead space air.
- C-D (Phase III) – The alveolar gas plateaus as there is almost complete saturation of CO_2 .
- Point D, End tidal CO_2 Concentration (EtCO_2) – The maximum CO_2 concentration that occurs during breathing as the dead space air is saturated with alveolar CO_2 gas. This also marks the end of expiration.
- D – E (Phase IV) – Inspiration begins. The inspired volume of fresh air quickly dilutes the CO_2 rich air.

Figure 117. An example of a time dependent CO_2 concentration profile in the upper airway for a single breath.

11.2 Experimental Procedure

The setup and experimental components for the capnography measurements are described in Chapter 5. The pulsatile pump was initialised with the healthy breath pattern which had a respiratory rate of approximately 14 breaths per minute and a tidal volume of 450 mL. Metabolic CO₂ production was replicated by bleeding CO₂ gas from the supply tank and into the pump cylinder to replicate a physiologically correct E_tCO₂. The CO₂ gas bleed rate was manually adjusted until an initial E_tCO₂ of 40 mm Hg was measured by the capnograph. This replicated the physiological alveolar CO₂ concentration (Tortora & Derrickson, 2011), however this measurement tended to fluctuate between 38.5 to 41 mm Hg. As a surrogate for the alveolar CO₂ concentration, the initial E_tCO₂ was measured at the trachea, as the airway model was limited to the upper airway. Once the CO₂ concentration reached a steady cycle, the experiment commenced. The CO₂ concentration was recorded for the airway regions summarised in Table 24. The capnography experiment was also carried out for NHFT assisted breathing at 30 L/min and 60 L/min flows. This was performed by first stabilizing the correct CO₂ gas concentration in the trachea, under a natural breathing condition (no therapy). Once E_tCO₂ of 40 mm Hg was achieved, the cannula was placed on the model and the therapy was administered. Before capnography testing could commence the CO₂ gas concentration had to reach an equilibrium with the therapy. The capnography results were recorded for approximately 20 breath cycles, which took 2 – 3 minutes. Each test was repeated 5 times. The capnography experiment was carried out for the rigid airway model and for each compliant conditions.

Table 24. Airway test regions for the capnography experiments

Region	Abbreviation	Tap number
Oral Cavity Left	OC L	5
Oral Cavity Right	OC L	6
Nasopharynx	NP	14
Velopharynx	VP	17
Oropharynx	OP	18
laryngopharynx	LP	23
Larynx	L	24
Trachea	Tr	28

11.3 Data Processing

The capnography data was recorded into partial pressure of CO₂ in mm Hg. The concentration was converted into a percentage volume fraction with the equation shown below. For each breath test, the recorded CO₂ concentrations were separated into individual breath cycles. These individual cycles were synchronised by using a cross

correlation function in MATLAB®. The raw, synchronised cycles were then phase averaged to develop a mean CO₂ concentration profile, similar to the example in Figure 117. This was performed for each tested region at each tested breathing condition. Each sample point on the CO₂ concentration profile has an uncertainty of 2 standard deviations, which was measured for each point of the mean CO₂ concentration profile from the phase averaging process.

$$\% F_{CO_2} = \frac{P_{CO_2}}{P_{Total}} \times 100 \%$$

Where $\% F_{CO_2}$ is the CO₂ percentage volume fraction, P_{CO_2} is the CO₂ gas partial pressure and P_{Total} is the atmospheric pressure (760 mm Hg).

11.4 Rigid Open Mouth Airway

The current section analyses the capnography results for the open mouth airway model with a rigid condition only. Figure 118 summarises the E_tCO₂ for all three tested breathing conditions (natural breathing, NHFT 30 L/min and 60 L/min) along the airway.

Figure 118. Mean E_tCO₂ throughout the rigid, open mouth airway. This is shown for natural breathing and NHFT at 30 L/min and 60 L/min. It should be noted that the E_tCO₂ for the NP and VP regions reduce to 0 % for the NHFT cases. Error bars correspond to an uncertainty of 2 standard deviations.

During natural breathing, the E_tCO₂ is consistent throughout all airway regions, with variation between 5 to 5.1 %. These results are within range of uncertainty, which varied between $\pm 0.1 \%$ to $\pm 0.3 \%$. These values also match the findings reported by Van Hove et al. (2016) who conducted capnography measurements experimentally and computationally for a rigid, closed mouth airway geometry. They found that the mean E_tCO₂ was consistent

throughout the pharynx of the airway at approximately 5 %, which is within 0.2 % of the alveolar CO₂ concentration. The current results are also within range of the physiological peak alveolar CO₂ concentration, which was approximated at the tracheal tap (tap 28) and corresponded to 5.1 ± 0.1 %.

With the application of NHFT at 30 L/min and 60 L/min, the mean CO₂ concentration in the nasopharynx and velopharynx (taps 14 and 17, respectively) reduced to 0 %. This was expected since, as shown in the flow rate measurements (Chapter 6) and supported by PIV studies by Spence (2011), all air is expired via the mouth, as there is a continuous supply of cannula flow entering the nasal cavity and travelling into the pharynx, throughout the respiration cycle (Figure 119). The nasopharynx and velopharynx regions only receive ‘fresh’, low CO₂ concentration air from the cannula; therefore during mouth open breathing with NHFT at 30 L/min, it can be said the nasal cavity, nasopharynx and velopharynx regions do not make up the anatomical dead space volume. In the current mouth open airway model, this washed out region had a volume of 38.8 mL which is approximately 51 % of the total airway model volume and 26 % of the typical adult human dead space volume (West, 2012).

Figure 119. PIV obtained flow profile adapted from Spence (2011), for open mouth breathing with NHFT at 30 L/min. This shows a sagittal cross section of the oral cavity, nasopharynx, velopharynx and oropharynx. Each image shows a different phase of the respiratory cycle. Images a to e correspond to expiratory phase and images f to h correspond to inspiratory phase.

With NHFT at 30 L/min, the regions between the oropharynx and trachea, referred to as the lower pharynx (taps 18, 23, 24 and 28), the $E_t\text{CO}_2$ reduced to values between $3.9 \pm 1.6 \%$ to $4.1 \pm 0.1 \%$. The $E_t\text{CO}_2$ measured in the lower pharynx regions all have similar concentrations to one another, as seen in the aforementioned natural breathing case. The pharyngeal $E_t\text{CO}_2$ during NHFT at 30 L/min falls by $19.7 \pm 3.2 \%$ to $21.7 \pm 5.2 \%$ of the natural breathing value. Similarly, during NHFT 60 L/min, the concentrations at the lower pharynx regions are all within uncertainty of each other and range from $3.8 \pm 0.2 \%$ to $3.9 \pm 0.2 \%$. The decrement in $E_t\text{CO}_2$ between natural breathing to NHFT assisted breathing at 60 L/min $22.3 \pm 5.1 \%$ to $23.2 \pm 7.8 \%$ of the corresponding natural breathing values. It can also be seen that the concentrations in each region of the pharynx are the similar at NHFT 30 L/min and NHFT 60 L/min, and are within range of uncertainty.

Table 25. Summary of mean $E_t\text{CO}_2$. The results by Van Hove et al. (2016) are the mean of their measured $E_t\text{CO}_2$ values in all tested pharyngeal regions (nasopharynx, velopharynx, oropharynx and trachea). The results for the current study show the mean of the $E_t\text{CO}_2$ values in the lower pharynx (taps 18, 23, 24 and 28).

Study	Mouth Condition	$E_t\text{CO}_2$		
		natural	NHFT 30 L/min	NHFT 60 L/min
Van Hove et al. (2016)	Mouth Closed	5 %	~ 4.5 %	~ 4.4 %
Current study	Mouth Open	$5.0 \pm 0.3 \%$	$4.0 \pm 0.2 \%$	$3.9 \pm 0.2 \%$

The current results for the open mouth rigid airway are compared to the studies by Van Hove et al. (2016), who also investigated NHFT washout mechanism, however did so with a closed mouth, rigid airway. These results are compared and summarised in Table 25. Unlike the open mouth model in the current study, the closed mouth airway used by Van Hove et al. (2016) did not experience a complete washout of CO_2 gas in the nasopharynx and velopharynx regions when applying NHFT levels of 30 L/min and above. Instead, the nasopharynx and velopharynx had similar CO_2 concentration to the remaining regions in the lower pharynx. These lower pharynx regions in the study by Van Hove et al. (2016) were greater to the lower pharynx $E_t\text{CO}_2$ values of the current study's open mouth results. During NHFT at both 30 L/min and 60 L/min, the mean $E_t\text{CO}_2$ of the lower pharynx in the open mouth model was $4.0 \pm 0.2 \%$ and $3.9 \pm 0.2 \%$ respectively and for closed mouth breathing by Van Hove et al (2016), this was approximately 4.5 % and 4.4 % respectively. The absolute difference in $E_t\text{CO}_2$ between open mouth and the reported closed mouth results corresponds to $0.5 \pm 0.2 \%$. It is evident that having the mouth open or closed during breathing can affect the washout mechanism provided by NHFT, with mouth open breathing experiencing a greater level of washout.

Figure 120 shows the mean CO_2 volume fraction in the laryngopharynx (tap 23) of the rigid mouth open airway model over one breath cycle for the three tested breathing conditions. There was no synchronisation between the flow rate and the capnography at the time of the recording, therefore data sets have been synchronised manually for comparison of the curves, using the cross-correlation function in Matlab®. Not only is there similarity of the $E_t\text{CO}_2$ between 30 L/min and 60 L/min profiles, there is also good alignment throughout phase III. This suggests that the effect NHFT has on $E_t\text{CO}_2$ plateaus at a flow rate of 30 L/min in mouth open breathing. However, the concentration profile of NHFT at 60 L/min has a smaller area, therefore the volume of flushed CO_2 must be greater compared NHFT 30 L/min.

Figure 120. CO_2 concentration profiles in the laryngopharynx (tap 23), for natural breathing and NHFT at 30 L/min and 60 L/min. Error bars correspond to an uncertainty of 2 standard deviations.

Two additional tests were carried out for the regions between the laryngopharynx to nasopharynx (tap 23, 18, 17 and 14) with NHFT levels of 10 L/min and 20 L/min. This was to determine the therapy flow rate where NHFT washout no longer reduced $E_t\text{CO}_2$ in the pharynx. The results are summarised in Figure 121 and it can be seen that at a NHFT level of 30 L/min the $E_t\text{CO}_2$ plateaus.

Figure 121. Mean $E_t\text{CO}_2$ in the airway carried out for natural breathing and NHFT (flow rates at 10, 20 30 and 60 L/min). Error bars correspond to an uncertainty of 2 standard deviations.

Going back to Figure 118, the $E_t\text{CO}_2$ values at the oral cavity (taps 5 and 6) during NHFT at 30 L/min are not similar or with uncertainty of the $E_t\text{CO}_2$ values in the lower pharynx regions, unlike for the natural breathing case. The oral cavity $E_t\text{CO}_2$ values decrease to $3.2 \pm 0.1 \%$ and $3.3 \pm 0.2\%$ for taps 5 and 6 respectively. This is also true for NHFT 60 L/min where the oral cavity $E_t\text{CO}_2$ values reduce to $0.9 \pm 0.1 \%$ and $1.8 \pm 0.2 \%$ for taps 5 and 6, respectively. The oral cavity experiences a greater level of CO_2 gas washout then the lower pharynx. Also, the oral cavity $E_t\text{CO}_2$ values at 60 L/min is not the same as those seen at 30 L/min, meaning that the oral cavity does not see a plateau in washout at 30 L/min.

PIV data by Spence (2011) shows that before and after peak inspiration occurs, there are two opposing streams in the pharynx (Figure 119f, h and a). The cannula jet from the NHFT flows downward passed the velopharynx toward the pharynx and simultaneously there is a laryngeal jet flowing upward from the larynx and leaves the airway via the oral cavity. In these phases of breathing, the washout mechanism can be seen, as the ‘fresh’ supply of cannula air flushes out the CO_2 rich air, causing dilution of the CO_2 gas in the pharynx and the oral cavity. During expiration, the cannula jet only washes out the nasal cavity, nasopharynx and velopharynx, before it exits directly out of the airway via the oral cavity (Figure 119b –e). As the cannula jet enters the oral cavity, it meets the upward laryngeal jet, which is high CO_2 concentration. A further reduction in CO_2 gas concentration occurs in the oral cavity as these two streams mix, and hence why the $E_t\text{CO}_2$ is lower in the oral cavity compared to the regions between the oropharynx and trachea. Although the PIV data in Figure 119 is limited to NHFT at 30 L/min only, the same reasoning can be used to explain the difference in oral cavity and lower pharyngeal CO_2 for the NHFT at 60 L/min case. However, an even greater reduction in oral cavity CO_2 concentration occurs due to the increase therapy flow rate. The PIV data also shows that during mouth open expiration, flow separation occurs in

the oral cavity, as the jet of expired air tends to detach from the surface of the tongue (Figure 119.d). Another contribution for the difference in oral cavity and lower pharynx $E_t\text{CO}_2$ is that the recirculation zones from the flow separation may influence gas mixing in the mouth, causing a dilution of CO_2 gas concentration.

Figure 122 shows the CO_2 profiles in the oral cavity for the different breathing conditions. With NHFT, the oral cavity CO_2 concentration profiles do not have the same shape as the typical curve shown in Figure 117 (section 11.1) and the profiles seen in the pharynx, represented by the laryngopharynx in Figure 120. It can be seen that during natural breathing, the concentration curve holds the typical shape of the CO_2 profile, but at 30 L/min, the profile tends to smooth out. However, the concentration curve shape is consistent between the right and left side of the oral cavity at NHFT 30 L/min.

At 60 L/min, the oral cavity concentration profiles change shape completely, and the left and right sides of the oral cavity show different curves. It is difficult to identify the $E_t\text{CO}_2$ for the CO_2 profile during NHFT 60 L/min as there was no distinguishable point on the curves in Figure 122 which marks the end expiration. It was estimated that phase III occurred between 1.5 to 2.5 s, in the oral cavity at 60 L/min, with $E_t\text{CO}_2$ occurring at 2.5 s. The left and right sides of the oral cavity vary significantly in $E_t\text{CO}_2$ during NHFT 60 L/min, where the left side (tap 5) has a CO_2 concentration of $0.9 \pm 0.1 \%$ and is nearly half of the right side (tap 6), which holds an $E_t\text{CO}_2$ of $1.8 \pm 0.2 \%$. If there was an asymmetrical air flow profile through the oral cavity, where the fresh air in the cannula jet tended to the left side during NHFT 60 L/min respiration, it would explain the results. This would lead to a non-uniform mixing of CO_2 gas which would cause higher concentrations of CO_2 gas on the right side of the oral cavity, compared to the left. Spence (2011), whose open mouth PIV studies were limited to NHFT at 30 L/min, did not report such a mechanism in his findings.

It is hypothesised that on expiration, as the cannula jet bends around the uvula, the geometry of the soft palate causes the flow to skew and favour the left side of the oral cavity. The asymmetry of the uvula (seen in Figure 123) supports this. Figure 123 shows a coronal cross-section from the posterior of airway model to reveal the soft palate insert. It can be seen that the uvula forms an 'M' like shape with the sagittal walls of the soft palate. The left side of the uvula recedes higher than the right side. It is hypothesised that the additional clearance on the left side of the uvula offers less resistance to the cannula jet during NHFT at 60 L/min, but not to the expired lung air flow which can explain why there are difference CO_2 concentrations on either side of the oral cavity.

Figure 122. CO₂ concentration profiles in the oral cavity (tap 5 (left) and tap 6 (right)) for natural breathing and NHFT at 30 L/min and 60 L/min. Error bars correspond to an uncertainty of 2 standard deviations.

Figure 123. Airway section model with dashed line denoting sectioning on the coronal plane (left) and resultant coronal section view of the soft palate insert from the posterior direction (right).

11.5 Compliant Soft Palate

The current section compares the capnography results between the rigid and compliant soft palate airway condition in the open mouth airway model. It was expected that out of all the compliant components, the soft palate would affect CO₂ gas mixing in the airway most significantly. This hypothesis was based on the results found from the pressure experiments, as the soft palate was the only compliant component to affect airway pressures and motion was observed during respiration with NHFT.

11.5.1 Natural Breathing

Figure 124 compares the capnography results during natural breathing for the rigid and compliant soft palate airway conditions. There is very good resemblance in E_tCO₂ between rigid and compliant soft palate conditions. The E_tCO₂ values of the compliant soft palate airway range between 4.9 ± 0.1 % to 5.1 ± 0.3 %, which are in range of the corresponding E_tCO₂ of the rigid airway. The absolute differences in E_tCO₂ between rigid and compliant airway are up to 0.1 %, and are less than the associated uncertainties. There is no statistically significant difference in E_tCO₂ between the rigid and compliant conditions, and therefore the soft palate compliance does not affect CO₂ gas mixing during natural breathing.

Figure 124. Mean E_tCO₂ concentrations along the airway during natural breathing for rigid and compliant soft palate airway conditions. This also shows the absolute difference in E_tCO₂ between compliant and rigid conditions. The error bars correspond to an uncertainty of 2 standard deviations.

11.5.2 NHFT 30 L/min

Figure 125 summarises the capnography results for NHFT 30 L/min, along with the absolute difference in between rigid and compliant $E_t\text{CO}_2$. The compliant soft palate $E_t\text{CO}_2$ values for the pharyngeal taps located in the lower pharynx (taps 28, 24, 23 and 18) ranged from $4.1 \pm 0.1 \%$ to $4.1 \pm 0.2 \%$ and the rigid $E_t\text{CO}_2$ for the same locations ranged from $3.9 \pm 0.2 \%$ to $4.1 \pm 0.1 \%$. The absolute difference between rigid and compliant $E_t\text{CO}_2$ values in the lower pharynx were all under 0.1% and each corresponding difference was less than its associated uncertainty. In the nasopharynx and velopharynx, the $E_t\text{CO}_2$ reduced to 0% in both rigid and compliant airways. As mentioned in the open mouth results (11.4), NHFT completely flushes the CO_2 rich air in these regions. There was no significant difference in $E_t\text{CO}_2$ between rigid and compliant soft palate conditions in all regions of the pharynx; therefore, soft palate compliance does not affect the mixing of CO_2 gas in the pharynx with NHFT assisted breathing at 30 L/min.

Figure 125. Mean $E_t\text{CO}_2$ concentrations along the airway during NHFT assisted breathing at 30 L/min. The results show for rigid and compliant soft palate airway conditions. This also shows the absolute difference in $E_t\text{CO}_2$ between compliant and rigid conditions. The error bars correspond to an uncertainty of 2 standard deviations.

On the left side of the oral cavity (tap 5) there is a difference in $E_t\text{CO}_2$ between rigid and compliant conditions. The $E_t\text{CO}_2$ for the rigid airway is $3.2 \pm 0.1 \%$ and the $E_t\text{CO}_2$ in the compliant airway is $3.5 \pm 0.2 \%$. This corresponds to an absolute difference of $0.4 \pm 0.2 \%$, and is deemed significant as it is outside the range of uncertainty. However, on the right side of the oral cavity (tap 6) the difference between rigid and compliant $E_t\text{CO}_2$ is $0.1 \pm 0.2 \%$, and is not statistically significant as the difference is less than its uncertainty.

Figure 126 shows the mean oral cavity CO_2 concentration profile, for a single breath during NHFT assisted breathing at 30 L/min. It is not clear where the $E_t\text{CO}_2$ point lies on the concentration profile on the right side of

the oral cavity for the compliant case (Figure 126 (right)). One would assume that the peak CO_2 concentration would suffice, but it appears that this occurs at the commencement of phase III, and approximately 1 s earlier than $E_t\text{CO}_2$ for the rigid airway. The $E_t\text{CO}_2$ for the compliant case was therefore estimated to occur at approximately 2.5 s, the same approximate time as for the rigid case. Although, the rigid and compliant curves have a similar $E_t\text{CO}_2$, it can be seen that the profiles of their respective phase III region do not align. The shapes of the remaining phases align well with one another. This suggests that the mixing of CO_2 gas remains consistent between rigid and compliant airways until peak expiration is reached.

There is a statistically significant difference between the left and right sides of the oral cavity in the compliant airway condition, and for the left side of the oral cavity, there is a statistically significant difference between rigid and compliant airway conditions. The differences in oral cavity CO_2 gas concentrations between rigid and compliant may be caused by soft palate motion, which was confirmed by endoscope during expiration for NHFT 30 L/min and 60 L/min. This may affect the interaction of the cannula jet and expired stream from the larynx or it may alter the aforementioned flow separation in the mouth and consequently influence the mixing of CO_2 gas in the oral cavity.

Figure 126. Mean CO_2 concentration profiles between rigid and compliant soft palate conditions in the oral cavity for NHFT 30 L/min. The graphs show the oral cavity left (left) and oral cavity right (right). The error bars correspond to an uncertainty of 2 standard deviations.

11.5.3 NHFT 60 L/min

With NHFT at 60 L/min, rigid vs compliant soft palate airway conditions yielded the similar outcomes as shown for the NHFT at 30 L/min (section 11.5.2). Figure 127 compares the $E_t\text{CO}_2$ between rigid and compliant conditions for NHFT assisted breathing at 60 L/min.

Figure 127. Mean $E_t\text{CO}_2$ concentrations along the airway during NHFT assisted breathing at 60 L/min. The results show for rigid and compliant soft palate airway conditions. This also shows the absolute difference in $E_t\text{CO}_2$ between compliant and rigid conditions. The error bars correspond to 2 standard deviations.

There is no statistically significant difference between the rigid and compliant $E_t\text{CO}_2$ in the pharynx. The $E_t\text{CO}_2$ values for the compliant soft palate airway range between 3.9 ± 0.3 % to 4.0 ± 0.2 % in the regions of the lower pharynx, and reduce to 0 % in the nasopharynx and velopharynx, and hence are not shown in Figure 127. The difference between compliant and rigid $E_t\text{CO}_2$ in the lower pharynx are below 0.1 % and are less than their associated uncertainties, which range between ± 0.1 % to ± 0.4 %.

On the left side of the oral cavity (tap 5), the $E_t\text{CO}_2$ of the compliant airway is 1.5 ± 0.2 %, and the $E_t\text{CO}_2$ of the rigid airway is 0.9 ± 0.1 %. This corresponds to a difference between rigid and compliant $E_t\text{CO}_2$ at tap 5 of 0.6 ± 0.2 %. The difference between the rigid and compliant CO_2 concentrations on the left side of the oral cavity can be explained with the same reasons for the NHFT 30 L/min case. It is thought that the motion of the compliant soft palate alters the interaction between the cannula jet and expired laryngeal streams, and hence affects the mixing of CO_2 gas in the oral cavity.

On the right side of the oral cavity (tap 6), the difference between rigid and compliant $E_t\text{CO}_2$ is 0.2 ± 0.4 % and is not statistically significant. Figure 128 shows the mean CO_2 concentration profiles in the oral cavity for a single

breath cycle. The rigid and compliant profiles on the right side of the oral cavity (Figure 128 (right)) align well for much of the breath cycle, with the exception of the end of phase III, however the rigid and compliant profiles agree within uncertainty at all times.

Figure 128. Mean CO₂ concentration profiles between rigid and compliant soft palate conditions in the oral cavity for NHFT at 60 L/min. The graphs show the oral cavity left (left) and oral cavity right (right). The error bars correspond to an uncertainty of 2 standard deviations.

11.6 Compliant Tongue

This section presents the capnography results for the open mouth airway with a compliant tongue condition. These results are compared to the rigid, open mouth airway results from section 11.4. The pressure tests for the compliant tongue airway condition concluded that tongue compliance does not affect airway pressures for the breathing conditions. It was hence expected that tongue compliance would not affect mixing of CO₂ gas during respiration.

Figure 129 summarises the mean $E_t\text{CO}_2$ values for the rigid and compliant tongue conditions during natural breathing. The $E_t\text{CO}_2$ throughout all tested sites of the compliant tongue airway condition are within range of uncertainty of each other and correspond to values between $4.9 \pm 0.2 \%$ to $5.2 \pm 0.2 \%$. There is no significant difference in $E_t\text{CO}_2$ between rigid and compliant tongue airway conditions, as the differences reached up to 0.1% and are less than their associated uncertainties, which range between $\pm 0.2 \%$ to $\pm 0.4 \%$. Therefore tongue compliance does not affect CO₂ gas mixing during natural breathing.

Figure 129. Mean $E_t\text{CO}_2$ during natural breathing for rigid and compliant tongue airway conditions. This also shows the absolute difference in $E_t\text{CO}_2$ between compliant and rigid conditions. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 130 summarises the mean $E_t\text{CO}_2$ values for the rigid and compliant tongue airway conditions during NHFT at 30 L/min. The outcome for NHFT at 30 L/min was similar to the natural breathing case as there was no statistically significant difference in $E_t\text{CO}_2$ between rigid and compliant tongue conditions. In the regions of the lower pharynx (taps 18, 23, 24 and 28) the absolute differences between rigid and compliant $E_t\text{CO}_2$ values reached up to 0.1 ± 0.3 %. For both rigid and compliant cases, complete washout of the nasal cavity, nasopharynx and velopharynx occurred, which had caused the nasopharynx and velopharynx (taps 14 and 17, respectively) CO_2 gas concentration to reduce to 0 %. In the oral cavity, rigid vs compliant $E_t\text{CO}_2$ differences were 0.1 ± 0.2 % and 0.2 ± 0.3 %. Once again, these differences are smaller than their associated uncertainty. Therefore, during NHFT assisted breathing at 30 L/min, CO_2 gas mixing is unaffected by tongue compliance.

Figure 130. Mean $E_t\text{CO}_2$ during NHFT assisted breathing at 30 L/min for rigid and compliant tongue airway conditions. This also shows the absolute difference in $E_t\text{CO}_2$ between compliant and rigid conditions. The error bars correspond to an uncertainty of 2 standard deviations.

The mean $E_t\text{CO}_2$ values during NHFT assisted breathing at 60 L/min are summarised in Figure 131. The differences in $E_t\text{CO}_2$ between rigid and compliant tongue condition are all under 0.1 % and are less than their corresponding uncertainties, which range from ± 0.1 % to ± 0.3 %. As seen in NHFT 30 L/min, the $E_t\text{CO}_2$ in the nasopharynx and velopharynx reduce to 0 % for both rigid and compliant conditions. There is no statistical significance in $E_t\text{CO}_2$ between compliant and rigid airway conditions.

Figure 131. Mean $E_t\text{CO}_2$ during NHFT assisted breathing at 60 L/min for rigid and compliant tongue airway conditions. This also shows the absolute difference in $E_t\text{CO}_2$ between compliant and rigid conditions. The error bars correspond to an uncertainty of 2 standard deviations.

11.7 Compliant Vocal Folds

The capnography measurements for the compliant vocal fold airway conditions were limited to the regions local to the site of compliance. These were the tracheal opening, larynx and laryngopharynx regions (taps 28, 24 and 23, respectively). The results from the pressure tests in concluded that compliant vocal folds did not affect the airway pressures for all breathing conditions. Based on these results, it was hypothesised that vocal fold compliance would not affect CO_2 gas mixing. Therefore, the capnography test was only carried out in the regions local to the vocal folds to confirm this hypothesis. Tests for the remainder of the airway regions would proceed if it were concluded that vocal fold compliance did affect CO_2 gas mixing.

Figure 132 summarises the $E_t\text{CO}_2$ in the compliant vocal fold airway, and compares against the rigid airway, for natural breathing. The compliant $E_t\text{CO}_2$ values resemble the corresponding rigid values, with differences under 0.1 % which are less than their corresponding uncertainties which range from ± 0.2 % to ± 0.3 %. Therefore there was

no statistically significant difference in CO₂ gas mixing between rigid and compliant vocal fold conditions during natural breathing.

Figure 132. Mean E_tCO₂ during natural breathing for rigid and compliant vocal fold airway conditions. This also shows the absolute difference in E_tCO₂ between compliant and rigid conditions. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 133 summarises the E_tCO₂ in the compliant vocal fold airway, and compares against the rigid airway, for NHFT assisted breathing at 30 L/min. As seen with the natural breathing case, the E_tCO₂ values for the compliant vocal folds resemble their corresponding rigid values, and they are within uncertainty. The difference between rigid and compliant E_tCO₂ is less than 0.1 % with the associated uncertainties at around ± 0.2 %, which exceeds the difference. Thus, it can be said that there is no significant difference in CO₂ gas mixing between rigid and compliant vocal fold conditions.

Figure 133. Mean E_tCO₂ during NHFT assisted breathing at 30 L/min for rigid and compliant vocal fold airway conditions. This also shows the absolute difference in E_tCO₂ between compliant and rigid conditions. The error bars correspond to an uncertainty of 2 standard deviations.

Figure 134 summarises the $E_t\text{CO}_2$ values of the rigid and compliant vocal fold airway conditions during respiration with NHFT at 60 L/min. In this breathing case, the outcomes are similar to those seen in natural and NHFT 30 L/min breathing for compliant vocal folds. The difference in $E_t\text{CO}_2$ between rigid and compliant conditions are all under 0.1 % and are less than their associated uncertainties, which range between ± 0.2 % and ± 0.3 %. Therefore, there is no statistical significance between rigid and compliant vocal fold conditions.

Figure 134. Mean $E_t\text{CO}_2$ during NHFT assisted breathing at 60 L/min for rigid and compliant vocal fold airway conditions. This also shows the absolute difference in $E_t\text{CO}_2$ between compliant and rigid conditions. The error bars correspond to an uncertainty of 2 standard deviations.

11.8 Conclusion

In the rigid, mouth open airway, CO_2 gas concentration was similar throughout all regions of the airway during natural breathing, ranging between 4.9 ± 0.1 % to 5.1 ± 0.2 %. During NHFT assisted breathing at 30 L/min and above, the CO_2 gas was completely washed out in the nasopharynx and velopharynx, reducing the $E_t\text{CO}_2$ of these regions to 0 %. During respiration with NHFT at 30 L/min, the $E_t\text{CO}_2$ of these regions reduced to approximately 4 %. The effect of the therapy's washout mechanism plateaued in these regions at 30 L/min, as similar $E_t\text{CO}_2$ values were reached with the application of NHFT at 60 L/min. With NHFT at 30 L/min and 60 L/min, the CO_2 concentration in the oral cavity was significantly lower compared to the regions in the lower pharynx. It was hypothesised that the interaction between the cannula jet and expired laryngeal stream caused further dilution of CO_2 gas in the oral cavity. It was also hypothesised that recirculation zones formed by flow separation in the oral cavity also caused more mixing and dilution of the CO_2 gas. Comparing open mouth rigid airway and closed mouth rigid, there were no differences during natural breathing. During NHFT at both 30 L/min and 60 L/min, the reported closed mouth airway had greater $E_t\text{CO}_2$ by 0.5 ± 0.2 % volume fraction. Therefore the open mouth airway experienced a greater level of CO_2 washout with NHFT.

The CO₂ concentrations in a compliant soft palate airway were the same as rigid during natural breathing. During NHFT assisted breathing at both 30 L/min and 60 L/min, the E_tCO₂ values in the pharynx of the compliant airway had no statistically significant difference when compared to the corresponding rigid values. The only region that was affected by soft palate compliance was the oral cavity. In the compliant soft palate airway, the left side of the oral cavity (tap 5) had greater CO₂ concentrations than the rigid airway. There was no statistically significant difference in E_tCO₂ between rigid and compliant airway for the right side of the oral cavity (tap 6). However, there was a statistically significant difference in CO₂ concentration profiles between rigid and compliant soft palate airways for both sides of the oral cavity and at both NHFT flows. It was hypothesised that during NHFT assisted breathing, the motion of the compliant soft palate altered the flow profile of the cannula and laryngeal streams as they entered the oral cavity on expiration, and ultimately affected the mixing of CO₂ gas in this region.

There was no statistically significant difference in E_tCO₂ between rigid and compliant tongue conditions, for all breathing conditions. Therefore, it can be concluded that tongue compliance did not have any effect on the mixing of CO₂ gas during respiration. This was also true for the compliant vocal fold condition.

12 Conclusion

This project explored how the passive properties of compliant soft tissues affected the upper airway during natural respiration and NHFT assisted respiration at 30 L/min and 60 L/min flows. A physical, open mouth airway model was constructed, which was anatomically accurate as it was based on medical CT scans, and fabricated with 3D printing processes. The model was designed to fit interchangeable tissue components, which could either simulate a rigid condition or a compliant condition. The purpose of this study was to evaluate whether the rigid airway assumption, which was used in previous computational and experimental studies, was a valid assumption. It was initially hypothesised that compliant airway tissues may be susceptible to flow induced motion or deformation and affect breathing. The compliant regions of interest, which this study focussed on, was the soft palate, tongue and the vocal folds. Two sets of these tissue components, which were referred to as inserts, were fabricated: a rigid set and a compliant set. The compliant inserts were cast in 3D printed moulds with a silicone resin at specific mixing ratios with a thinning oil. The mixing ratios achieved a material elastic modulus which matched that of the biological tissue, and hence compliance could be simulated. Each compliant tissue was individually tested for, and hence four airway conditions were studied: A rigid airway, compliant soft palate airway, compliant tongue airway and a compliant vocal fold airway. The casts gave accurate representations of the tissue components, however they tended to have a greater surface roughness than their rigid counterparts. The ABS moulds had a lower quality surface finish, which is inherent to the printer, and this directly impacted the casts. The airway model also underwent warping due to the heat effects from support material removal. Realignment was achieved, however not completely, hence the model was not an exact representation of the original geometry used. A removable gasket was also designed for the airway which sufficiently sealed the model as it gave a leak rate of 3 % at an internal pressure of 400 Pa, which was over twice as high as the greatest airway pressure measured in this project.

Flow rate at the mouth and nose were measured at peak expiration and peak inspiration during breathing, to understand how flow was partitioned. During natural inspiration, distribution between mouth and nose was 49 % and 52 % of the inspiratory demand, respectively and with NHFT at 30 L/min this changed to 26.4 % and 73.6 %, respectively. This was because NHFT biases inspiration towards the noses. During NHFT 60 L/min, 152 % of inspiratory demand entered via the nasal passage, as therapy was over twice that of inspiratory demand. The excess air exited the airway via the mouth. During natural expiration, the distribution between mouth and nose was 47.8 % and 52.2 % of all air exiting the airway, respectively; and with NHFT 30 L/min, this changed to 55 % and 45 % of the total flow leaving the airway, respectively. In the nasal passage, 13.8 % of the therapy flow persisted. At NHFT 60 L/min the outward flow from the leak area and mouth corresponded to 45.9 % and 54.2 % of the total flow leaving the airway, respectively, with 30.7 % of therapy flow persisting through the nasal passage.

The static pressure tests determined that the soft palate was the only compliant tissue that affected the airway pressures, for both natural and NHFT assisted breathing. During natural breathing at peak inspiration the compliant soft palate airway condition had more negative pressures in the pharynx, than the rigid condition by $15.5 \pm 5.7 \%$ to $35.3 \pm 12.1 \%$ of the corresponding peak-to-peak rigid pressures. The compliant airway had greater pressures in the oral cavity, than the rigid, by an average of $25.0 \pm 22.1 \%$. During peak expiration, the compliant soft palate airway had greater pressures in pharynx, than rigid airway, by $3.8 \pm 2.6 \%$ to $10.7 \pm 2.7 \%$, and lower pressures in the oral cavity by $9.0 \pm 5.5 \%$, compared to rigid. Although no soft palate motion was observed with the endoscopic camera during natural breathing, it was hypothesised that the compliant soft palate moved to the posterior on inspiration, causing a narrowing of the velopharynx and widening of the oral-to-pharynx passage; and it moved anterior on expiration, causing the opposite change in geometry. This influenced the partitioning of the airflow between oral and nasal passages, and increased the overall resistance of the airway, hence more pronounced pressures at peak inspiration and expiration. During inspiration with NHFT at 30 L/min, the only difference between rigid and compliant airway pressures was at the velopharynx, local to the site of compliance. The pressure at the velopharynx was greater in the compliant airway by $8.0 \pm 5.5 \%$, compared to the rigid. The hypothesis was made that the uvula tended posteriorly due to slumping, which acted as a constriction, increasing the local resistance only, and hence the local upstream pressure. During peak expiration with NHFT at 30 L/min, the compliant soft palate airway condition had greater pressures than the rigid, by $9.3 \pm 1.1 \%$ to $23.7 \pm 5.5 \%$ throughout the entire airway. The endoscopic camera revealed that the soft palate tended to move toward the anterior upon expiration. Because all air was expired via the mouth with NHFT at 30 L/min, the hypothesis was made that the soft palate motion restricted the exiting flow causing an increase in resistance and hence a global increase in airway pressure. During peak inspiration with NHFT at 60 L/min, the compliant airway also experienced a global increase in airway pressures and were greater than the rigid pressures by $6.7 \pm 4.6 \%$ to $20.6 \pm 7.6 \%$. No observable motion of the soft palate was seen with the endoscope but it was hypothesised that there was a combination of anterior bulging at the velopharynx due the distending effects of the therapy, and posterior uvula slumping. As there was a portion of air exiting via the mouth during inspiration with NHFT 60 L/min, the soft palate motion restricted this airflow and caused an increase in the resistance of the compliant airway and hence increase the peak inspiratory airway pressures. During peak expiration with NHFT at 60 L/min, once again, a global increase in peak pressures occurred for the compliant airway, and these were greater than rigid pressures by $27.9 \pm 4.4 \%$ to $45.6 \pm 10.7 \%$. The endoscopic camera revealed a greater anterior motion of the soft palate, which was cycled with inspiration and expiration. The global pressure increase of the compliant airway can be explained with the same mechanisms as in expiration at 30 L/min, only that the effects were more pronounced due to a greater therapy flow. The pressure results from the compliant tongue and compliant vocal fold conditions showed that there was no statistically significant difference when comparing against the results from the rigid model. Therefore, the tongue and vocal fold compliance did not affect breathing.

The capnography results for a rigid mouth open airway were compared to reported closed mouth airway data. During natural breathing the rigid, open mouth airway the $E_t\text{CO}_2$ varied between 5.0 to 5.1 % but they were within uncertainty and within the alveolar CO_2 concentration. With NHFT at 30 L/min the $E_t\text{CO}_2$ for the nasopharynx and the velopharynx reduced to 0 %, indicating that with mouth open breathing, the CO_2 gas in the nasal cavity, nasopharynx and velopharynx regions is completely flushed and these regions are removed from the dead space. This was due to a continuous cannula flow through the nasal passage, even during inspiration. In the lower pharynx regions, $E_t\text{CO}_2$ was between 3.9 to 4.1 %, and these were within range of uncertainty with each other. The same outcomes were seen for NHFT at 60 L/min as the washout mechanism of the therapy plateaued after 30 L/min. The oral cavity experienced the most significant washout, with an average $E_t\text{CO}_2$ of $3.3 \pm$ and $1.4 \pm$ for NHFT 30 L/min and 60 L/min respectively. The CO_2 rich expired laryngeal stream met with fresh cannula air in the oral cavity, causing further dilution of the CO_2 gas. The capnography results for the open mouth rigid model were compared to reported results obtained from a closed mouth airway. During natural breathing there was no difference in CO_2 concentration throughout the pharynx of the airway, between the current study's open mouth model and the reported study's closed mouth model. With the application of NHFT at 30 L/min and 60 L/min, it was found that the reported results for the closed mouth model had greater $E_t\text{CO}_2$ values in the lower pharynx by 0.5 ± 0.2 % volume fraction. The nasopharynx and velopharynx of the closed mouth airway experienced the same $E_t\text{CO}_2$ measured in the lower pharynx regions.

The soft palate was the only compliant tissue to affect CO_2 gas mixing and this was limited to the left side of the oral cavity only, during NHFT assisted breathing. The $E_t\text{CO}_2$ of the left side of the oral cavity in the compliant airway was greater than that of the rigid airway by 0.4 ± 0.2 % during NHFT 30 L/min respiration and greater by 0.6 ± 0.2 % during NHFT 60 L/min respiration. It was hypothesised that the motion of the compliant soft palate affected the laryngeal and cannula stream as they entered the oral cavity, and hence affected the mixing of CO_2 gas. There was no statistical significance in CO_2 concentration between rigid and compliant soft palate conditions for the entire airway during natural breathing, and for the pharynx of the airway during NHFT assisted breathing. The compliant tongue and the compliant vocal folds did not affect the mixing of gas for all breathing conditions.

This study can conclude that out of the three tested tissues, only soft palate compliance affected breathing pressures and CO_2 gas mixing. Therefore, a rigid condition for the soft palate is not a valid assumption when modelling the human upper airway, but it is a valid assumption for the tongue and vocal folds. However, the study into compliance was limited to an open mouth airway geometry and it has been shown, both by previous studies and in the current study that closed mouth breathing causes greater airway pressures. It would be expected that with greater airway pressures, the flow would exert a greater force on the compliant regions; therefore it cannot be stated that that vocal fold and tongue compliance do not effect breathing in a closed mouth case. Also, the airway in this

study was based on a single person. Although the elastic modulus was a realistic replication for the biological tissues, the behaviour of the tissues is a result of material properties, and geometry of the tissue and the surrounding airway region. There will always be variation in airway geometry between people, therefore the findings from this study are not representative of an entire population. Tissue compliance was simulated by replicating the elastic portion of the tissue's viscoelastic properties. The viscous (loss) portion was neglected due to the limited information for both tissue and resin properties. The compliant tissue simulants were also assumed to be homogeneous and isotropic; but in reality the tissues are comprised of multiple layers with varying levels of compliance, and they may exhibit different behaviour in different directions. It is unknown to what extent these parameters may have on the behaviour of the tissues, however, to replicate compliance with more accuracy, they must be considered. In an *in vivo* airway there is constant involuntary muscle activity in the compliant regions. This alters the shape of the airway. Also, muscle activation changes the tone of the tissue, and tissues' compliance is rate dependent. In the current study, the compliant tissues represented a passive state, and muscle activation was not considered.

13 Future Work

An interchangeable, compliant airway model, the first of its kind, was designed and fabricated specifically for this project. Throughout this study, the limitations of the model became apparent, and these involved general practicality of the model and features that could affect results. The airway model required complete disassembly when interchanging the rigid or compliant inserts, as these were encased within the airway shell. This involved removal of the bolts and taking apart the two halves of the airway shell to gain access to the internal geometry of the model. Not only was this a time consuming process, but since it exposed the entire internal surface of the airway passage, it ran the risk of misalignment of the airway seal; risked misalignment of the other removable components; or risked introducing foreign objects which could interfere with the flow and have the potential to compromise the results. Because of the frequent assembling and disassembling, it was common to inadvertently over-tighten the bolts. The polymer material of the model lacked the durability for this type of treatment and small fractures would occasionally occur towards the completion of this project. An improvement to the airway design would be to isolate each removable insert so that they could be removed individually without having to deconstruct the airway model.

The printer of choice was the inkjet photopolymer Projet HD 3000, which was desired for its accuracy and surface finish. It also used wax as its support material, which was advantageous for this application as it could easily be removed from the complicated geometry of the airway, by simply melting it. The alternative 3D printing approach was to use the Objet Connex, which was also a photopolymer process, and gave similar, desirable accuracy and surface finish; however, this option was ruled out as water blasting was required to flush out and remove the support material, which was thought to be ineffective on the complicated geometry of the airway model. In retrospect, the Projet printer may not have been the best candidate for the fabrication process, as the heat required to melt the wax also caused a small degree of warping on the airway model. This was detrimental to the model as the resultant geometry was not completely faithful to the original anatomy it was based on. The distortion effects of the heat could be avoided with the Objet printer, therefore design features, which could improve the water blasting method for the airway model, should be explored; or a test should at least be carried out to confirm whether the water blasting method is effective on an Objet Connex printed airway model.

In previous studies into compliance, compliance was simulated by using a silicone composition that matched the elastic modulus of the relevant biological tissues. This was carried out using A-341 silicone gel at specific ratios of Dow Corning thinning oil, which were identified in a previous study by Kashif et al (2013). It was originally intended to simulate the compliance of the relevant tissues by replicating both the storage (elastic) modulus, to represents the elastic portion and the loss modulus, which represents the viscous portion of a viscoelastic material.

Material additives would need to be explored, so that the silicone could produce the desired elastic and loss properties of the relevant biological tissues. It was also desired to replicate the shear modulus and the Poisson's ratio of the compliant tissues of interest. To carry out this material study, dynamic material analysis (DMA) was required, which is used to quantify viscoelastic properties of polymers. In DMA a cyclic stress is applied on a material sample, and the material is characterized by examining its dynamic response. This aspect of the project was discontinued as the appropriate equipment to proceed with the DMA testing was unavailable, hence it is intended as a future study.

From this project there is now a better understanding of how compliance can affect natural and NHFT assisted breathing. However, the research was limited to one airway geometry, representative of a single person. This raises the question: are the effects that have been observed specific to the current patient, or would similar trends be expected for other airway geometries? To properly answer this question, the sample size of the study needs to be expanded, or a similar study should be conducted on a mean airway model which is representative of a sub-group or population. Also, the compliance tests were limited to an open mouth airway geometry. It has been discussed that for a closed mouth breathing condition, airway resistance increases, and hence greater pressures are observed. It would be interesting to investigate how compliance affects breathing in closed mouth airway. In this project the breath waveform used was representative of a healthy adult. Further testing should be carried out on a breathing waveforms which can simulate respiratory disorders such as COPD or asthma.

Now that it has been shown that soft palate compliance affects breathing, a more rigorous testing approach can be applied to further understand the mechanisms in play and the flow pattern within a compliant airway. Particle imaging velocimetry (PIV) is a flow visualization technique that can quantify the velocity field in a flow domain. This experimental method has been used previously in various airway studies, however it has been limited to rigid boundary conditions. The use of PIV to test airway compliance would introduce new challenges in the airway model design process. As PIV is based on imaging data, the models used need to be made from a transparent material with a refractive index that matches the working fluid so that the boundaries of the model do not disturb transmitted light. A compliant PIV airway model would require an investigation into a material which can match a working fluid, and an elastic modulus which matches the biological tissue.
